COMMITTEE ON SOCIETY HEADQUARTERS — *Chairman*, Frank R. Ober, Charles G. Mixer, Michael A. Tighe, Daniel B. Reardon, Albert A. Hornor

COMMITTEE ON FINANCE — *Chairman*, Francis C. Hall, Ernest L. Hunt, Charles F. Wilinsky, Edward J. O'Brien, Jr., Peer P. Johnson

COMMITTEE ON INDUSTRIAL HEALTH — *Chairman*, Dwight O'Hara, vice-chairman, Thomas L. Shipman; Joseph C. Aub, Daniel L. Lynch, John R. Agnew, Louis R. Daniels, John G. Downing

OFFICERS OF THE SECTIONS

SECTION OF MEDICINE

Chairman, Albert A. Hornor, Boston, *vice-chairman*, Daniel J. Ellison, Lowell, *secretary*, Francis C. Hall, Boston

SECTION OF SURGERY

Chairman, Charles F. Twomey, East Lynn, *secretary*, Alexander J. A. Campbell, Boston **EXECUTIVE COMMITTEE** — Stanley J. G. Nowak, Belmont and Boston (1 year), Edward L. Young, Jr., Brookline and Boston (2 years), E. Parker Hayden, Brookline and Boston (3 years).

SECTION OF PEDIATRICS

Chairman, Floyd R. Smith, Pittsfield, *secretary*, Gerald N. Hoefel, Cambridge **EXECUTIVE COMMITTEE** — *Chairman*, Philip H. Sylvester, Boston; James Marvin Baty, Belmont and Brookline, Leroy T. Stokes, Haverhill

SECTION OF OBSTETRICS AND GYNECOLOGY

Chairman, Arthur F. G. Edgelow, Springfield, *vice-chairman*, William J. McDonald, Boston, *secretary*, George Van S. Smith, Brookline

SECTION OF RADIOLOGY

Chairman, George Levene, Chestnut Hill and Boston, *secretary*, Edward B. D. Neuhauser, Cambridge and Boston.

SECTION OF PHYSIOTHERAPY

Chairman, Arthur L. Watkins, Arlington and Boston, *secretary*, Howard Moore, Newton and Boston

SECTION OF DERMATOLOGY AND SYPHILOLOGY

Chairman, Bernard Appel, Lynn, *secretary*, Fenner A. Chace, F. River

OFFICERS OF THE DISTRICT MEDICAL SOCIETIES FOR 1944-1945

BARNSTABLE — *President*, Joseph N. Kelly, Orleans, *vice-president*, Harold F. Rowley, Harwich Port, *secretary*, Julius G. Kelley, Pocasset, *treasurer*, Frank Travets, Barnstable, *librarian*, Carroll H. Keene, Chatham, *executive and public-relations counselor*, William D. Kinney, Osterville, *legislative counselor*, Julius G. Kelley, Pocasset

BERKSHIRE — *President*, Floyd R. Smith, Pittsfield; *vice-president*, Thomas H. Nelligan, Pittsfield, *secretary*, N. Newell Copeland, Pittsfield, *treasurer*, Daniel N. Beers, Pittsfield, *executive counselor*, Isaac S. F. Dodd, Pittsfield, *legislative counselor*, Clement F. Kernan, Pittsfield, *public-relations counselor*, Patrick J. Sullivan, Dalton

BRISTOL NORTH — *President*, Joseph L. Murphy, Taunton, *vice-president*, William M. Stobbs, Attleboro, *secretary*, William J. Morse, Attleboro, *treasurer*, Joseph V. Chatigny, Taunton, *executive counselor*, William H. Allen, Mansfield, *legislative counselor*, Ralph M. Chambers, Taunton, *public-relations counselor*, James H. Brewster, Attleboro

BRISTOL SOUTH — *President*, Russell Wood, New Bedford, *vice-president*, John C. Corrigan, Fall River, *secretary and treasurer*, Albert H. Sterns, New Bedford, *executive and legislative counselor*, Edwin D. Gardner, New Bedford, *public relations counselor*, Harold E. Perry, New Bedford

ESSEX NORTH — *President*, John T. Batal, Lawrence, *vice-president*, Percy J. Look, Andover, *secretary*, Harold R. Kurth, Methuen, *treasurer*, Guy L. Richardson, Andover, *secretary*, Paul Nettle, Bradford, *executive counselor*, Frank W. Ganley, Methuen, *legislative counselor*, Edward H. Harold R. Kurth, Methuen

ESSEX SOUTH — *President*, Edwin D. Reynolds, Danvers, *vice-president*, William R. Irving, Gloucester, *secretary*, Henry D. Stebbins, Marblehead, *treasurer*, Charles F. Deering, Danvers, *executive and public-relations counselor*, Loring Grimes, Swampscott, *legislative counselor*, Charles A. Worthen, Lynn

FRANKLIN — *President*, Kenneth H. Rice, South Deerfield, *vice-president*, John B. Temple, Shelburne Falls, *secretary and treasurer*, Harry L. Craft, Ashfield, *executive and public-relations counselor*, William J. Pelletier, Turners Falls, *legislative counselor*, Howard M. Kemp, Greenfield

HAMPDEN — *President*, John E. Dwyer, Springfield, *vice-president*, Merrill F. Hosmer, Longmeadow, *secretary and treasurer*, George C. Steele, West Springfield, *executive and legislative counselor*, William A. R. Chapin, Springfield, *public-relations counselor*, Patrick E. Gear, Holyoke

HAMPSHIRE — *President*, Arthur N. Ball, Northampton, *vice-president*, Joseph D. Fallon, Northampton, *secretary and treasurer*, Mary P. Snook, Chesterfield, *librarian*, Abbie M. O'Keefe, Northampton, *executive counselor*, L. Beverly Pond, Easthampton, *legislative counselor*, Arthur N. Ball, Northampton, *public-relations counselor*, Alfred J. Bonnevill, Hatfield

MIDDLESEX EAST — *President*, Joseph H. Kerrigan, Stoneham, *vice-president*, Justin L. Anderson, Reading, *secretary*, Roy W. Layton, Melrose, *treasurer*, Albert E. Small, Melrose, *librarian*, Raymond J. Miltzer, Woburn, *executive counselor*, Edward M. Halligan, Reading, *legislative counselor*, John M. Wilcox, Woburn.

MIDDLESEX NORTH — *President*, James J. Cassidy, Lowell, *vice-president*, William J. Wiggin, Lowell, *secretary*, Brendan D. Leake, Lowell, *treasurer*, Mason D. Bryant, Lowell, *executive counselor*, William F. Ryan, Lowell, *legislative counselor*, Archibald R. Gardner, Lowell, *public-relations counselor*, Daniel J. Ellison, Lowell

MIDDLESEX SOUTH — *President*, Harold G. Giddings, Newton Centre, *vice-president*, Brainerd F. Conley, Malden, *secretary*, Alexander A. Lev, Newton Centre, *treasurer*, Fabian Packard, Belmont, *orator*, Varazta H. Kazanjian, Belmont, *executive counselor*, Dwight O'Hara, Waltham, *legislative counselor*, Brainerd F. Conley, Malden, *public-relations counselor*, John P. Nelligan, Cambridge

NORFOLK — *President*, Albert Ehrenfried, Brookline, *vice-president*, Dean S. Luce, Canton, *secretary*, Charles J. E. Kickham, Jamaica Plain, *treasurer*, Frederick Reis, Jamaica Plain, *executive counselor*, Charles J. Kickham, Brookline, *legislative counselor*, Humphrey L. McCarthy, West Roxbury, *public-relations counselor*, Norman A. Welch, West Roxbury

NORFOLK SOUTH — *President*, Frank W. Jenkins, Braintree, *vice-president*, Braintree, *secretary*, David L. Bartlett, Wollaston, *treasurer*, A. Bartlett, Wollaston

PLYMOUTH — *President*, Peirce H. Leavitt, Brockton, *vice-president*, Paul B. J., Brockton, *secretary*, C. McLeod Brockton, *treasurer*, Rudolph J. Weller, Bridgewater, *executive counselor*, John J. Weller, Bridgewater, *legislative counselor*, John J. Weller, Bridgewater, *public-relations counselor*, Charles D. McCann, Brockton

SUFFOLK — *President*, Donald Munro, Boston, *vice-president*, Charles C. Lund, Boston, *secretary*, Robert L. Goodale, Boston, *treasurer*, Richard S. Eustis, Boston, *executive counselor*, Donald Munro, Boston, *legislative counselor*, William E. Browne, Boston, *public-relations counselor*, Albert A. Hornor, Boston

WORCESTER — *President*, Benjamin H. Alton, Worcester, *vice-president*, Charles R. Abbott, Clinton, *secretary*, Leslie P. Leland, Worcester, *treasurer*, Edward P. Disbrow, Worcester, *librarian*, John Fallon, Worcester, *executive counselor*, Ralph S. Perkins, Worcester, *legislative counselor*, Lester M. Felton, Worcester, *public-relations counselor*, John Fallon, Worcester

WORCESTER NORTH — *President*, Herman D. Bone, Gardner, *vice-president*, Rudolf F. Bachmann, Fitchburg, *secretary*, Edward A. Adams, Fitchburg, *treasurer*, Frederick H. Thompson, Jr., Fitchburg, *executive counselor*, C. Bertram Gay, Fitchburg, *legislative counselor*, Francis A. Reynolds, Athol, *public-relations counselor*, James V. McHugh, Leominster

CASE RECORDS
OF THE MASSACHUSETTS GENERAL HOSPITAL

WEEKLY CLINICOPATHOLOGICAL EXERCISES

FOUNDED BY RICHARD C. CABOT

TRACY B. MALLORY, M.D., *Editor (on leave of absence)*
BENJAMIN CASTLEMAN, M.D., *Acting Editor*
EDITH E. PARRIS, *Assistant Editor*

VOLUME 30

1944

INDEX

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

1944.

The date of publication of any case may be determined from the case number. The first two figures of each case number indicate the volume number. The third and fourth figures give the number of the week, dating from January 1. The last figure gives the case number for the week. For example, Case 30251 is the first case for the 25th week of Volume 30.

- Abscess of groin, 30271
 - of kidney, 30382
 - of lung, 30491
- paravertebral, 30271
- perinephric, 30271
- peritoneal, 30311
- psoas, 30271
- subdiaphragmatic, 30311
- Actinomycosis of salpinx and ovaries, 30181
 - of retroperitoneal and retropleural spaces, kidney and liver, 30081
- Addison's disease, 30231
- Adenoma of parathyroid, 30122
- Adrenal gland, pheochromocytoma of, 30051
 - tuberculosis of, 30231
- Aneurysm of aorta, with rupture, 30512
 - dissecting, healed, 30341
 - recent, 30341, 30212
 - mycotic, of sinus of Valsalva (tuberculous), 30091
 - syphilitic (?), with rupture, 30281
 - (See also Syphilis)
- Anomaly, congenital, bicuspid aortic valve, 30102
 - coarctation of aorta, 30402
 - short esophagus, 30411
- Aorta, coarctation of, 30402
 - (See also Aneurysm)
- Artery, endarteritis, pulmonary, 30012
 - occlusion of orifices of, renal, 30052
 - periarteritis nodosa, generalized, 30201
 - (See also Aneurysm, Embolism, Heart, Thrombosis)
- Bile duct, carcinoma of, 30381
 - stone in, 30372
 - stricture of, traumatic, with biliary fistula, 30482
- Bone, carcinoma of, metastatic (sacroiliac region), 30121
 - dysplasia of, fibrous (ilium), 30121
 - Ewing's tumor of (ilium), 30352
 - fibroma of, neuro- (femur), 30401
 - osteitis fibrosa, 30282
 - osteoarthritis of (hip), 30131
 - (See also Joint)
- Bone marrow, myeloma of, plasma cell, 30251
 - tuberculosis of, milary, 30091
- Brain, embolism of, 30272
 - hemorrhage of, 30221
- Bronchiectasis, 30492
- Bronchiolitis fibrosa obliterans, 30031
- Bronchus, cyst of, extrapulmonary, 30471
 - tuberculosis of, 30152
- Carcinoid, malignant, of ileum, with metastases to regional lymph nodes, 30241
- Carcinoma of bile duct, 30381
 - of colon, 30071, 30362
 - of esophagus, 30192
 - of gall bladder, with fistulous extension into duodenum and transverse colon, 30302
 - of kidney, 30021, 30442
 - of lung, 30082, 30132, 30211
 - of pancreas, 30032, 30252, 30462
 - of rectum, 30382
 - of sigmoid, 30482
 - with ileosigmoidal fistula, 30232
 - of stomach, 30092, 30141
 - of ureter, 30432
 - metastatic, of sacroiliac region, 30121
- Cholelithiasis, 30372
- Cirrhosis, see Liver
- Colitis, see Intestine
- Colon, see Intestine
- Coma, diabetic, 30451
- Cyst, bronchiogenic, extrapulmonary, 30471
 - pancreatic, 30101
- Diabetes mellitus, 30351, 30451
- Diabetic coma, 30451
- Diaphragm, hernia of, with bleeding from ulcer of herniated portion of stomach, 30171
 - with short esophagus, 30411
- Diverticulitis, see Intestine
- Dysplasia of bone, fibrous (ilium), 30121
- Embolism, cerebral, 30272
 - mesenteric (arterial), 30111
 - pulmonary, 30221
- Empyema, 30222, 30342
- Endarteritis, see Lung
- Endocarditis, see Heart
- Enteritis, see Intestine
- Esophagus, anomaly of, congenital, short esophagus, 30411
 - carcinoma of, with metastases to mediastinal and retroperitoneal lymph nodes, pancreas and esophagus, 30192
 - hernia of, diaphragmatic, with bleeding from ulcer at herniated portion of stomach, 30171
 - ulcer of, peptic, 30411
- Ewing's tumor of ilium, 30352
- Femur, fibroma of, neuro-, 30401
- Fibroma, neuro-, of femur, 30401
 - of spinal cord, 30452, 30472
- Fibromyomatosis of uterus, 30162
- Fibrosis, alveolar, of lung, 30521
- Fistula, biliary, 30482
 - cholecystoduodenal, 30302
 - cholecystocolic, 30302
 - gastrocolic, 30071
 - ileosigmoidal, 30232
- Gall bladder, carcinoma of, with fistulous extension into duodenum and transverse colon, 30302
 - (See also Cholelithiasis)
- Gangrene of small intestine, 30201
- Gastritis, see Stomach
- von Gierke's disease (?) of heart, 30402
- Glomerulosclerosis, intercapillary, 30351
- Glycogen storage disease (von Gierke)? of heart, 30402
- Heart, anomaly of, congenital, bicuspid aortic valve, 30102
 - coarctation of aorta, 30402
 - coronary disease of, thrombosis, 30292, 30431, 30501, 30521
 - cor pulmonale, 30012
 - endocarditis, bacterial, subacute, aortic (pneumococcus Type 13), 30102
 - auricular, 30272
 - mitral, 30272
 - rheumatic, acute, aortic, with stenosis, 30272
 - mitral, with regurgitation, 30182
 - with stenosis, 30272
 - tricuspid, with stenosis, 30272
 - chronic, aortic, 30431, 30461
 - with stenosis, 30012, 30361
 - mitral, 30461
 - with stenosis, 30012, 30361, 30431
 - tricuspid, 30361

- subacute, aortic, 30431
- mitral, with stenosis, 30431
- von Gierke's disease of (?), 30402
- hypertrophy of, 30182
- idiopathic, 30111, 30391
- infarct of, myocardial, 30292, 30431, 30441, 30501, 30521
- myocarditis, interstitial, and generalized perivascular infiltration (sulfonamide idiosyncrasy), 30441
- pericarditis, acute, 30031
- stenosis of, calcareous, aortic, 30461
- thrombus, mural, auricle and ventricle, 30391, 30501, 30521
- Hemorrhage into lung, 30212
 - into stomach, massive, 30192
 - cerebral, 30221
- Hepatitis, see Liver
- Hernia, diaphragmatic, with bleeding from ulcer of herniated portion of stomach, 30171
 - with short esophagus, 30411
- Hip, osteoarthritis of, 30131
 - synovitis of, pigmented villonodular, 30131
 - tuberculosis of, 30142
- Hodgkin's disease, see Lymphoma
- Ileum, see Intestine
- Ilium, fibrous dysplasia of, 30121
 - Ewing's tumor of, 30352
- Infarct of heart, 30292, 30431, 30441, 30501, 30521
 - of intestine (small), 30111, 30141, 30261, 30511
 - of liver, 30511
 - of lung, 30501
 - of spleen, 30511
- Intestine, carcinoid, malignant, of ileum, with metastases to regional lymph nodes, 30241
 - carcinoma of, 30071, 30362, 30382, 30482
 - with ileosigmoidal fistula, 30232
 - colitis, ulcerative, 30491, 30522
 - diverticulitis of (sigmoid), 30151, 30481
 - with perforation, 30151
 - enteritis, regional, 30172
 - fistula of, cholecystoduodenal, 30302
 - cholecystocolic, 30302
 - gastrocolic, 30071
 - ileosigmoidal, 30232
 - gangrene of (small intestine), 30201
 - infarct of, 30111, 30141, 30261, 30511
 - lymphoma of, clasmatocytic, with extension to ovary, 30222
 - lymphoblastic, 30191
 - with perforation, 30011
 - obstruction of, 30261
 - tuberculosis of, 30321
 - volvulus of, 30421, 30422
- Jaundice, obstructive, 30482
- Joint, carcinoma of, metastatic, sacroiliac region, 30121
 - osteoarthritis of, 30131
 - synovitis of, pigmented villonodular, 30131
 - tuberculosis of, 30142
- Kidney, abscess of, 30382
 - actinomycosis of, 30081
 - carcinoma of, 30021, 30442
 - glomerulosclerosis, intercapillary, 30351
 - polycystic disease of, congenital, 30301, 30412
 - sulfonamide nephropathy, 30392
 - tuberculosis of, 30062, 30091, 30242
 - (See also Nephritis, Nephrolithiasis, Pyonephrosis)
- Krukenberg tumor of ovary, 30112
- Larynx, tuberculosis of, miliary, 30062
- Liver, actinomycosis of, 30081
 - atrophy of, subacute, yellow, 30041
 - cirrhosis of, alcoholic, subacute, 30371
 - biliary, intrahepatic cholangitic, 30262
 - cardiac, 30012, 30461
 - portal, 30091
 - toxic, 30022, 30122, 30522
 - hemorrhage of, 30212
 - hepatitis, acute, 30022, 30271
 - hemorrhagic, with toxic cirrhosis, 30491
 - infarct of, 30511
 - myeloma of, plasma-cell, 30251
 - polycystic disease of, congenital, 30301
 - tuberculosis of, 30091, 30271
- Lung, abscess of, 30492
 - bronchiolitis fibrosa obliterans, 30031
 - carcinoma of, oat-cell, 30082, 30132, 30211
 - embolism of, 30221
 - empyema of, 30322, 30342
 - endarteritis of, 30012
 - fibrosis of, alveolar, 30521
 - infarct of, 30501
 - pneumonia of, broncho-, 30322
 - lipid, 30192
 - lobar (Friedländer's bacillus), 30332
 - (Type 14 pneumococcus), 30342
 - pneumonitis, chronic, 30291
 - thrombosis of (?embolic), 30012
 - tuberculosis of, 30062, 30091, 30522
- Lymphoma, malignant, clasmatocytic, of ileum, with extension to ovary, 30222
 - lymphoblastic, of small intestine, 30191
 - with perforation, 30011
 - of stomach, 30072
- Mediastinum, sarcoid of (lymph nodes), 30331
- Meninges, tuberculosis of, miliary, 30062
- Mole, hydatidiform, 30161
- Mongolism, 30201
- Myeloma, plasma-cell, of liver and bone marrow, 30251
- Myocardium, see Heart
- Nephritis, embolic, 30102, 30272
 - glomerulo-, acute, 30361
 - chronic, 30282, 30392
 - pyelo-, acute, 30392
 - with multiple abscesses, 30382
- Nephrolithiasis, 30442
- Osteoarthritis of hip, 30131
- Ovary, actinomycosis of, 30181
 - lymphoma of, malignant (clasmatocytic), 30222
 - Krukenberg tumor of, 30112
- Pancreas, carcinoma of, 30332, 30252, 30462
 - metastatic, with perforation into stomach, 30192
 - cyst of, 30101
 - degeneration of, hydropic (islets of Langerhans), 30451
 - infiltration of, lymphocytic, 30451
- Pancreatitis, acute, hemorrhagic, with fat necrosis, 30262
- Parathyroid adenoma, 30122
 - hyperplasia of, secondary, 30282
- Periarteritis nodosa, generalized, 30201
- Pericardium, see Heart
- Peritoneum, abscess of, 30311
 - carcinoma of, metastatic, 30462
 - tuberculosis of, 30522
- Pheochromocytoma of adrenal gland, 30051
- Pneumonia, see Lung
- Pneumonitis, see Lung
- Prostate, tuberculosis of, 30242
- Pyonephrosis, 30442
- Rectum, see Intestine
- Salpinx, actinomycosis of, 30181
- Sarcoid of mediastinal lymph nodes, 30331
 - of spleen, 30312
- Sacroiliac region, carcinoma of, metastatic, 30121
- Sarcoma, Ewing's tumor, of ilium, 30352
 - fibro-, neurogenic, of subscapular region, 30042
- Septicemia (Friedländer bacillus), 30332
- Sigmoid, see Intestine
- Sinus of Valsalva, aneurysm of (tuberculous), 30091
- Spinal cord, fibroma of, neuro-, 30452, 30472
- Spine, tuberculosis of, miliary, 30062
- Spleen, infarct of, 30511
 - rupture of, 30202
 - sarcoid of, 30312
 - tuberculosis of, 30091, 30271
- Stomach, carcinoma of, 30092, 30141
 - fistula of, gastrocolic, 30071
 - hemorrhage of, 30192
 - hernia of, diaphragmatic, with bleeding from ulcer of herniated portion of stomach, 30171
 - with short esophagus, 30411
 - lymphoma of, lymphoblastic, 30072

Stricture of common bile duct, traumatic, with biliary fistula, 30482

Sulfonamide idiosyncrasy (interstitial myocarditis and generalized perivascular cellular infiltration), 30441
nephropathy, 30392

Synovitis, pigmented villonodular, of hip, 30131

Syphilis (?), of aorta, 30281

Thrombosis of atrium, occluding right pulmonary veins, 30521
of celiac axis, 30511

of cystic artery, 30511

of hepatic artery, 30511

of mesenteric artery, 30501

of mesenteric vein, 30111, 30141

of portal vein, 30022, 30111, 30122, 30141

of pulmonary artery (? embolic), 30012

of splenic artery, 30511

of splenic vein, 30022, 30141

of subclavian vein, 30211

(See also Heart)

Tuberculosis of adrenal gland, 30231, 30271

of aorta (*sinus of Valsalva*), with mycotic aneurysm, 30091

of bronchus, 30152

of hip, 30142

of ileum, 30321

of jejunum, 30321

of kidney, 30242

of lung, 30062, 30091, 30522

of lymph nodes, 30321

of peritoneum, 30522

of prostate, 30242

of vertebra, 30061, 30271

miliary, of bone marrow, 30091

of kidney, 30062, 30091, 30522

of larynx, 30062

of liver, 30091, 30271, 30522

of lung, 30062, 30522

of meninges, 30062

of spine, 30062

of spleen, 30091, 30271, 30522

Tumor, Ewing's, of ilium, 30352

Krukenberg, of ovary, 30112

Ulcer of esophagus, peptic, 30411

Ureter, carcinoma of, 30432

Uterus, fibromyomatosis of, diffuse intravascular, with extension to broad ligament, 30162

mole of, hydatidiform, 30161

Vein, carcinoma of, metastatic, 30021

thrombosis of, 30022, 30111, 30122, 30141, 30211

Vena cava, carcinoma of, metastatic, 30021

Vertebra, tuberculosis of, 30061

with paravertebral, psoas, groin and perinephric abscesses, 30271

Volvulus of intestine, 30421, 30422

SUBACUTE DEGENERATION OF THE BRAIN IN PERNICIOUS ANEMIA*

RAYMOND D. ADAMS, M.D.,† AND CHARLES S. KUBIK, M.D.‡

BOSTON

PERNICIOUS anemia is a complicated disease that is characterized by certain changes in the blood and blood-forming organs, in the gastrointestinal tract and in the central nervous system. The primary fault is thought to be an atrophy of the gastric mucosa that induces a deficiency of certain substances essential for the maturation of red cells. The cause of the nerve-fiber degeneration is more obscure, but it has been suggested that deficiency of another factor may account for it. The most important pathologic findings are hyperplasia of the bone marrow, consisting chiefly of the less mature elements of the red-cell series, atrophy of the lingual and gastric mucosa, a variable amount of hemosiderosis in the spleen, liver and kidneys and, in many cases, degeneration of spinal white matter, especially in the posterior and lateral columns. Less well known, and in fact not even mentioned in many textbooks on neurology, are the lesions in the cerebral white matter. Because of this we feel justified in reporting the following observations in 2 cases.

Only within comparatively modern times have the neurologic aspects of pernicious anemia been fully appreciated. Although Lichtheim¹ in 1886 was the first to describe the spinal-cord pathology, Russell, Batten and Collier² in 1900 were the first to publish a full clinical and pathological description of subacute combined degeneration.

In the early part of the nineteenth century there were several references to the brain lesions of pernicious anemia in the papers of Wohlwill,³ Ransohoff,⁴ Braun,⁵ Schröder⁶ and others, but most of them were concerned with findings of dubious significance, such as petechial hemorrhages and changes in cerebral blood vessels. Preobrajensky⁷ in 1902 was one of the first to mention degeneration of cerebral white matter, but the abstract of his

paper contains such meager clinical and pathological data that the diagnoses of pernicious anemia may be questioned.

Lube⁸ in 1913 described cases of pernicious anemia in which he found miliary foci of myelin degeneration in the cerebral white matter. The lesions were said to be globular or oblong, 80 to 100 microns in diameter and closely related to blood vessels.

Barrett⁹ in 1913 reported the pathological findings in 6 psychotic patients dying of what was thought to be pernicious anemia, although in most of these cases there were not sufficient data to establish the diagnosis—according to present-day standards. Unfortunately, his material was not well adapted to clinicopathological correlation, because many of these patients had been admitted to the psychiatric ward with obvious depressions or paranoid schizophrenia long before the onset of their terminal illness. In most of them confusion and disorientation developed after the onset of the anemia. On post-mortem examination there was degeneration in the cerebral white matter in only 1 of the 6 cases; in the other 5 cases only an alteration of cortical nerve cells was thought to be present.

Pfeiffer¹⁰ in 1915 reported an unquestionable case of pernicious anemia in which mental symptoms, consisting of drowsiness, inattentiveness, confusion and disorientation, were outspoken features. Post-mortem examination disclosed, in addition to slight alteration of cortical nerve cells, degeneration of the medullated nerve fibers in the white matter of the frontal lobes.

Woltman¹¹ in 1918 reported 7 cases in all of which there were lesions in the cerebral white matter similar to those described by Lube, Barrett and Pfeiffer. His paper contains the largest series and the most complete description of the brain lesions.

Since then, although clinicians have continued to show an interest in the psychiatric aspects of this disease, as indicated by the publication of many clinical studies, the neuropathology has been neglected. Only a few scattered case reports, including those by Lurie¹² in 1919, Weimann¹³ in 1924 and Lebensart¹⁴ in 1934, have appeared in recent

acid in the fasting gastric contents or after injection of histamine. The cerebrospinal fluid showed normal pressure. The total protein was 37 mg. per 100 cc., and the Wassermann reaction was negative. The urine gave a + test for albumin, and contained many white-blood cells.

The patient developed fever, tachypnea and signs of pulmonary consolidation. Following five injections of con-

Microscopic Findings

Cerebrum. Lesions were found in the central and convolutional white matter of the cerebral hemispheres, the cerebellar peduncles and, in Case 2, the optic tracts near the chiasm. The characteristic changes in the cerebrum were best demonstrated in sections stained for myelin. In these preparations the affected white matter was diffusely but unevenly pale, the unevenness being due to a more pronounced degeneration in some regions, usually around blood vessels (Figs. 1, 2, 3, 4 and 5). In many such foci, varying in size from 50 to 150 microns the myelin was completely degenerated. The axis cylinders as well as myelin sheaths were affected, though possibly not to the same extent. In the perivascular zones of more severe degeneration there were numerous macrophages filled with fat (Fig. 6). The astrocytes and oligodendrocytes were increased in number throughout the white matter, but more so just beneath the cortical gray matter than in the deeper white matter, where the myelin

FIGURE 2. *Degeneration of White Matter in the Right Occipital Lobe (Case 1 Weigert stain).*

centrated liver extract the reticulocyte count rose to 8 per cent on the 5th hospital day. Death occurred suddenly on the 8th day.

The anatomical diagnoses were pernicious anemia with subacute degeneration of the spinal cord and brain, pulmonary embolus and acute pyelonephritis.

MORBID ANATOMY

The pathological findings were so nearly alike in these 2 cases that the following description applies equally to both.

Gross Findings

Gross changes in the central nervous system were relatively inconspicuous. There was no atrophy of cerebral convolutions or enlargement of the ventricles. The leptomeninges were transparent, and the large cerebral arteries were not especially atherosclerotic. In Case 1 (after fixation in formalin) there were innumerable minute gray foci on the cut surface of the white matter, which gave it a mottled appearance. These were approximately 1 mm. in diameter and were disseminated through all parts of the centrum and corpus callosum and, to a slight degree, the convolutional white matter. No such gross changes were observed in Case 2.

On the cut surface of the spinal cord in both cases the white matter in the posterior and lateral and to a lesser extent the ventral columns was gray and translucent. These changes were most marked in the thoracic and cervical portions.

FIGURE 3. *Degeneration in Internal Capsule and Corpus Callosum (Case 2 Weigert stain)*

was more severely degenerated. The astrocytes had large cell bodies and cytoplasmic processes that were distinctly stained in Nissl preparations. The nerve cells in the cerebral cortex were not remarkable. There were no swollen cells with eccentric nuclei and chromatolysis, such as are commonly observed in pellagra and some other vitamin-deficiency diseases.

years, and in these no attempt was made to relate the mental symptoms to the brain pathology.

CASE REPORTS

CASE 1. A 54-year-old Italian woman was in good health until approximately 6 months before admission in August, 1941, to the Boston City Hospital. At first she began to tire easily and complained of paresthesia, first in the feet and legs and a few weeks later, in the hands and arms. The legs gradually became weak and finally, shortly before entry, she could not walk. She lost control of her bladder and bowels. Admission was precipitated by the acute onset of pleuritic pain, cough and fever. The patient was said to have acted queerly for the last several weeks, but it was impossible to obtain a clear account of the mental symptoms from her relatives.

On admission, the temperature was 103°F., the pulse 90, the respirations 28, and the blood pressure 130/80. The patient appeared to be in a fairly well-nourished condition.

and anisocytosis were observed in a blood smear. The icteric index was 5.0. Examination of the cerebrospinal fluid showed normal pressure and no cells. The total protein was 38 mg. per 100 cc. The gold-sol curve was 1221000000. Wassermann and Davies Hinton tests were negative. Gastric analysis showed no free hydrochloride. X-ray examination of the chest showed consolidation of the hilar portions of both lungs.

Concentrated liver extract was given parenterally in doses of 10 cc. each day for 7 successive days. Sulfathiazole was administered because of the lung findings and fever. On the 4th hospital day the reticulocytes in the blood rose to 14 per cent and on the 6th day to 22 per cent. The patient remained in a stuporous condition for several days and was only beginning to appear more alert on the 8th hospital day when she suddenly died.

The anatomical diagnoses were pernicious anemia with subacute degeneration of the spinal cord and brain, pulmonary embolus and femoral phlebothrombosis.

CASE 2. A 53-year-old Italian woman was admitted to the Massachusetts General Hospital on July 15, 1941. She

FIGURE 1. *Diffuse, Uneven Degeneration of White Matter in a Precentral Convolution (Case 2; Spielmeier stain).*

The skin and mucous membranes were pale. She was drowsy and inattentive, making no effort to respond to many of the questions asked and answering others in monosyllables. So far as could be ascertained she was not melancholic but rather apathetic. When pressed on any point, such as details of history, she became decidedly irritable. Memory for recent events was poor. She was oriented as to place and person but gave the year as 1928. The ocular movements and pupillary reflexes were normal. The tongue was red and smooth and came out in the midline without tremor. The arms could be moved but were very weak, and the legs were almost completely paralyzed. There was no atrophy of muscles. The patient was incontinent of urine and feces. Tendon reflexes could barely be elicited in the arms and were absent in the legs. The plantar reflexes were extensor in type and abdominal reflexes were absent. All forms of sensation were reduced in the arms and almost entirely absent in the legs. The only other physical findings were dullness of the chest on percussion, bronchial breath sounds and a friction rub over the base of the right lung.

The hemoglobin was 62 per cent, and the red-cell count 1,000,000. The white-cell count was 6000, with 2 per cent reticulocytes. The hematocrit was 26.9 per cent, the mean corpuscular volume 139 cubic microns, and the mean corpuscular hemoglobin content 35.9 per cent. Poikilocytosis

had had paresthesias in the legs and hands for 2 years. During the 3 months prior to admission there was progressive loss of strength in the legs and finally inability to walk. There had been precipitancy of urination and occasional incontinence. A few days before entry to the hospital she developed pain in the left flank and burning and frequency of urination. There were no remarks in the record concerning the mental status of the patient, but when admitted to another hospital a short time before, it was noted that she was vague as to details of her illness, irritable and difficult to manage. She left against the advice of the physician before a diagnosis could be made.

On admission, the temperature was 99°F., the pulse 90, the respirations 20, and the blood pressure 95/65. The patient appeared to be in a fair state of nutrition. The skin and mucous membranes were pale. Because of marked language difficulty details of mental status were not obtained. On one occasion restraint was necessary. The arm and trunk muscles were weak, and the legs were almost completely paralyzed. There was no muscular atrophy. Vibratory and position sense in the legs were absent. Tendon reflexes were absent in the legs and the plantar reflexes were extensor in type. There was incontinence of feces and urine.

The hemoglobin was 70 per cent. The red-cell count was 2,500,000 with 4 per cent reticulocytes. There was no free

ders as well as the myelin sheaths were destroyed. There was an unevenness similar to that of the brain lesions, which was more conspicuous in longitudinal than in cross sections (Fig. 8). The areas of more pronounced degeneration seemed to have no relation to blood vessels. Fat-filled macrophages were abundant. There was singularly little reaction of astrocytes, although they had increased

in our experience, do they resemble the findings observed in pellagra or the central neuritis of Meyer.¹⁵ In our cases of pellagra the columns of Goll were degenerated throughout their course as in secondary degeneration from a dorsal-root lesion; this process was not uneven as in pernicious anemia and was accompanied by a pronounced gliosis. No degeneration of cerebral white matter was observed.

FIGURE 6. *An Area of Nerve-Fiber Degeneration (Case 1, fat stain).*

somewhat in size and possibly in number. Nerve cells in the spinal cord were not remarkable.

DISCUSSION

Subacute Degeneration of Brain

The findings in these cases confirm the observations of others that cerebral lesions may occur in pernicious anemia. Furthermore, the cerebral and spinal-cord lesions are almost exactly alike. In both, the essential pathology consists of a more or less diffuse though uneven degeneration of the white matter, with little or no proliferation of fibrous glia. Because of this similarity it seems reasonable to suppose that this degeneration of cerebral white matter is as specifically related to pernicious anemia as is subacute combined degeneration of the spinal cord.

These changes are unique and quite unlike those that occur in cerebrovascular disorders, multiple sclerosis, Schilder's diffuse periaxial encephalitis and other more chronic degenerative diseases. Nor,

Moreover, there were swelling and central chromatolysis of the anterior-horn cells and of the larger pyramidal cells of the cerebral cortex, whereas nothing remotely resembling this was found in our cases of pernicious anemia. Although it is true that degeneration of the corticospinal tracts in pellagra has been reported by others, this too may be secondary to destruction of Betz cells in the motor cortex.

Certain authors have reported small hemorrhages and nerve-cell changes in the brain in pernicious anemia. Small, recent perivascular or capillary hemorrhages so often occur as a terminal event in many diseases that they are not of any great significance. The matter of nerve-cell changes is more difficult to assess. In some papers the descriptions are too ambiguous to permit accurate interpretation, whereas in others nonspecific changes, such as shrinkage and pigmentary atrophy, have been assigned undue importance. Where nerve-cell swelling and central chromatolysis like that of pellagra were present (Barrett,⁹ Pfeiffer¹⁰ and

DISCUSSION

Subacute Degeneration of Brain

The findings in these cases confirm the observations of others that cerebral lesions may occur in pernicious anemia. Furthermore, the cerebral and spinal-cord lesions are almost exactly alike. In both, the essential pathology consists of a more or less diffuse though uneven degeneration of the white matter, with little or no proliferation of fibrous glia. Because of this similarity it seems reasonable to suppose that this degeneration of cerebral white matter is as specifically related to pernicious anemia as is subacute combined degeneration of the spinal cord.

These changes are unique and quite unlike those that occur in cerebrovascular disorders, multiple sclerosis, Schilder's diffuse periaxial encephalitis and other more chronic degenerative diseases. Nor,

Moreover, there were swelling and central chromatolysis of the anterior-horn cells and of the larger pyramidal cells of the cerebral cortex, whereas nothing remotely resembling this was found in our cases of pernicious anemia. Although it is true that degeneration of the corticospinal tracts in pellagra has been reported by others, this too may be secondary to destruction of Betz cells in the motor cortex.

Certain authors have reported small hemorrhages and nerve-cell changes in the brain in pernicious anemia. Small, recent perivascular or capillary hemorrhages so often occur as a terminal event in many diseases that they are not of any great significance. The matter of nerve-cell changes is more difficult to assess. In some papers the descriptions are too ambiguous to permit accurate interpretation, whereas in others nonspecific changes, such as shrinkage and pigmentary atrophy, have been assigned undue importance. Where nerve-cell swelling and central chromatolysis like that of pellagra were present (Barrett,⁹ Pfeiffer¹⁰ and

Woltman¹¹), the possibility of associated factors such as malnutrition and vitamin B deficiency cannot be dismissed.

Relation of Subacute Degeneration of Brain to Subacute Combined Degeneration of Spinal Cord and to Pernicious Anemia

Just as degeneration of the posterior columns seems to be the initial event in subacute combined

anemia and brain and spinal-cord lesions exactly like those in our cases. In cases such as these it is obviously possible that the gastric condition bears no causal relation to pernicious anemia or subacute degeneration.

Relation between Brain Lesions and Mental Symptoms

It is a well-known fact that patients with subacute combined degeneration often exhibit mental symp-

FIGURE 7. Subacute Combined Degeneration (Weigert stain).

There is an uneven degeneration of spinal white matter in the posterior, lateral and anterior columns. Note the cribriform appearance and the relative symmetry of the lesions.

degeneration, so do spinal-cord changes usually, if not invariably, precede the brain changes. Clark¹⁶ and Greenfield and O'Flynn¹⁷ have shown that the posterior columns are first affected, and that when both lateral and posterior columns are involved the oldest lesions are in the latter. In this connection, many cases have been described in which there were spinal-cord lesions without brain lesions, but in all authentic reports of subacute degeneration of the brain there have been spinal-cord lesions. Thus it seems that the order of involvement of the central nervous system is posterior columns, then lateral and anterior columns and finally cerebral white matter.

That pernicious anemia, with or without subacute combined degeneration, may develop as a consequence of carcinoma of the stomach or of gastric resection is suggested by a few carefully studied cases. Similarly, Bertrand and Ferraro¹⁸ have reported a case of gastric carcinoma with macrocytic

toms that vary from slight irritability and suspiciousness to a marked confusional psychosis. The question naturally arises as to the relation between these symptoms and the pathologic changes observed in the brain. Some writers, notably Pfeiffer,¹⁰ Barrett⁹ and Lurie,¹² affirm a causal relation, whereas Woltman¹¹ concludes that well-marked psychoses have little or nothing to do with the destroyed areas. In reviewing Woltman's case material, however, one finds mental symptoms such as irritability, mental sluggishness, fluctuation in attention and delirium in all the cases in which the mental status was recorded (Table 1).

The observation of degeneration in the optic tracts provides an explanation for reports of impaired vision by Cohen,¹⁹ Turner²⁰ and others. In our case the record gives no information concerning vision. Bickel²¹ has also reported foci of degeneration in the optic nerves of a patient with subacute combined degeneration of the spinal

8 (Woltman ¹¹)	48	M	1.0	18	—	+	Impaired sensation, Romberg sign	Marked fluctuation in attention	+	Scattered areas of myelin degeneration in cerebrum
9 (Woltman ¹¹)	51	M	2.0	50	—	+	Paresthesia ataxia and impaired sensation Babinski sign	Inattentive faulty memory depressed mood and logical thinking disordered	Degeneration of posterior and lateral columns	Degeneration of nerve fibers in occipital lobes
10 (Woltman ¹¹)	42	M	0.8	18	—	+		Delirious, talkative and restless	+	Degeneration of nerve fibers in focal areas of cerebral white matter
11 (Weimann ¹³)	55	F	—	37	1.3	+	Paresthesia incontinent sphincters ataxia and spasticity	Defective memory ideas of persecution, disoriented and demented	Posterolateral sclerosis	Focal lesions in cerebral white matter and diffuse gliosis
12 (Lebensart ¹⁴)	45	M	—	65	1.2	+	Paresthesia weakness ataxia sensory loss and plantar reflexes	Stuporous and drowsy	+	Status spongiosus in cerebral white matter with proliferation of macrophages
13 (Adams and Kubik — Case 1)	54	F	—	50	—	+	Paresthesia weakness incontinence loss of reflexes impaired sensation and Babinski sign	Confused disoriented, poor memory and stuporous semi-comatose	Degeneration of posterior, lateral and anterior columns	Focal and diffuse degeneration of nerve fibers in cerebral white matter, corpus callosum, cerebral peduncles and brain stem
14 (Adams and Kubik — Case 2)	53	F	2.5	70	—	+	Paresthesia weakness incontinence loss of tendon reflexes and Babinski sign, some sensory loss	Irritable and unreasonable, restraint because of mental confusion	Degeneration of posterior, lateral and anterior columns	Uneven degeneration of nerve fibers in cerebral white matter, optic chiasm and cerebellar peduncles

cord. In his case there were bilateral central scotomas and optic atrophy.

On the basis of these observations we favor the supposition that both subacute combined degeneration of the spinal cord and subacute degeneration of the brain represent an advanced stage in a specific process that is induced by a deficiency of certain substances necessary to the metabolism of myelinated nerve fibers. It is not to be expected that

An analysis of our cases and others indicates that patients with brain lesions have mental symptoms. The converse is not necessarily true, since cerebral lesions are not always found in cases in which mental symptoms have been present.

Note the resemblance between the cord lesions and the brain lesions

every patient with pernicious anemia will have demonstrable brain lesions, but all those in whom there are definite and widely disseminated brain lesions will probably have mental disorders.

SUMMARY

The clinical and pathological findings in 2 cases of pernicious anemia with subacute degeneration of the brain and spinal cord are described. In each, there were well-marked neurologic and psychiatric symptoms.

The important pathologic changes consisted of a diffuse uneven degeneration of nerve fibers in the spinal cord and cerebral white matter, with relatively little proliferation of fibrous glia. The brain lesions resembled the cord lesions so closely that there could be little doubt concerning their identity.

The pathologic process is unique and easily distinguished from that of other diseases involving the cerebral white matter and from that of pellagra.

PART-TIME PROTECTIVE ENVIRONMENT AND WORKING PAROLE AS AN ADJUVANT IN THE TREATMENT OF ALCOHOLISM

JOSEPH THIMANN, M.D.*

BOSTON

ASIDE from other considerations, — physiologic, psychologic and sociologic, — the extremely high cost to cities, states and the federal government of the care of alcoholic patients who become a public liability has been noted so often by writers on the subject that it would be duplication to quote them at length here. The seriousness of the problem from the economic viewpoint, however, is summed up in the following statement from a paper read by Dr. Merrill Moore at the fifty-first annual meeting of the Association of Life Insurance Medical Directors of America (October 17 and 18, 1940), entitled "Alcoholism: A public health problem":

Its [alcoholism's] cost to the individual, the family and the community cannot be expressed in simple figures, for it involves such intangible and remote costs as the tax rate on your real property, the amount of money available in a tax dollar for schools and roads and the dividends which certain of your well-invested securities yield. When one reckons the cost of caring for chronic alcoholics in jails and for acute alcoholics in hospitals, the resulting figure represents only the surface cost. Persons with alcoholic psychoses increase the budget of the Massachusetts State Department of Mental Health by 10 per cent; broken homes resulting from alcoholism cause municipal and federal budgets for relief to be greatly increased; the costs incident to accidental deaths which are indirectly due to the intemperate use of alcohol are tremendous.

This is looking at the problem from the negative side. When one attempts to deal with it in a positive way, he must answer the questions, "How can this economic waste be prevented?" and "How can an alcoholic patient be helped toward physical, emotional and economic rehabilitation?" A plan that has been worked out at the Washingtonian Hospital, although it may not answer these questions fully and finally, at least seems to be a signpost indicating the way.

This is a system of working patients; that is, the patient, while still under treatment, returns to his former occupation (or finds a new job), but spends all his free time at the hospital. This arrangement has a number of advantages. The patient is in a protected environment during his free time. His evenings and nights are spent at the hospital if he

is working in the daytime or his daytime hours if he is working at night, and he is under the shelter of the hospital over week ends, a time difficult to bridge if he is living outside because of the temptation to seek the conviviality of a tavern in his loneliness and because he has nothing to do. He is, moreover, removed from the emotional instability of a home environment in which the wife or mother may have little understanding of his problem, and from the company of drinking companions. He is put on his feet financially, so that he can pay, or at least contribute to, his hospital fee and the charge for special treatment, such as the conditioned-reflex therapy. He becomes, while still under treatment, gradually more self-reliant and responsible, and self-respecting. He is in daily contact with the physician, so that psychotherapeutic interviews may help him over difficult periods.

Under this arrangement, patients whose maladjustment to life caused an acute intoxication every few weeks, with resulting inability to hold a job and be self-supporting, have worked daily and efficiently without recourse to alcohol. In some cases this has been so even before the conditioned-reflex treatment was given or psychotherapy could be expected to bear results. The patients were rid of the vicious cycle of relapses, which caused despondency and lack of faith that they would ever be abstinent, which, in turn, led again to drinking. On working parole they have gained self-confidence and self-assurance from the realization that they are being abstinent and are economically successful. Thus they grow increasingly better able to adjust to the difficulties of life, to face reality and to become poised and happy people.

CASE I. A. B., a 38-year-old Nova Scotian, who worked as a painter in a local shipyard, was admitted to the hospital in December, 1942. He was deeply intoxicated on admission, having been drinking continuously for 3 days. According to his story, he had his first drink at the age of 18 and drinking became a problem when he was 28. At the time he entered the hospital, he was drinking a quart of whisky daily and some beer and his longest period of sobriety had been 4 months. He gave as the cause of his drinking marital difficulties.

The hospital social worker was requested to interview the patient's sister and to secure a complete social history, which, in abstract, was as follows: The patient's parents were

*Medical director, Washingtonian Hospital.

natives of Nova Scotia. His father was a strict disciplinarian, a dominant person and definitely the head of the household. His mother was a mild woman, gentle and sympathetic, and there was a close tie between the patient and her. The patient was always especially interested in the mature, aggressive, masculine type of girl who is fond of sports. At the age of 26 he married a girl who was, according to the patient's sister, an aggressive, irresponsible person. There were three children by the marriage. Almost from the beginning there was much incompatibility between the patient and his wife, and after 7 years they separated. Later they became reconciled, but 4 years after the first separation they again separated and the patient went to live with his sister. Throughout the years of his marital difficulties, the patient turned frequently for help to his two sisters, who were described as fine, intelligent women with high standards but rather moralistic, repressive and critical in their attitudes.

After he had been in the hospital for 2 weeks, the patient expressed a desire to take the conditioned-reflex treatment, which was begun on December 28. The preliminary series of treatments was finished on January 5, 1943. With the assistance of the social worker, arrangements were made for the patient to return to his former place of employment on January 11. It was explained to the employer that he had come voluntarily to the Washingtonian Hospital and had been co-operative in treatment plans, and, as he had always been a good worker, his employer was willing to rehire him.

The patient was advised to live at the hospital. He was given a low rate for his board, and after he began working he assumed this obligation himself.

From February 7 until July 12, the patient had four reinforcements of the conditioning treatment. During this period, also, he was in close contact with the medical director of the hospital, the hospital social worker and the social worker at the referring agency. He earned sufficient pay to meet his hospital bills, contribute to the care of his children and pay the first installment on his income tax.

On August 16, the patient injured his ankle while at work and was transferred to a general hospital. Because this injury made climbing stairs inadvisable he could not return to the Washingtonian Hospital. He was, however, persuaded to come in for week-end stays and to make short visits to the physician during the week. He has now been totally abstinent for eighteen months.

CASE 2. C. D., a 43-year-old American citizen of Canadian birth, began drinking at the age of 17 and had never been abstinent since then. Drinking became a problem 4 years before entrance to the hospital, when he realized that he was unable to stop and that this habit was interfering with his work. He was referred to the hospital by the Court that found him guilty of drunkenness. There had been innumerable arrests for the same offense, and he had been confined at the Bridgewater State Farm six times. When drunk he was belligerent and dangerous.

According to the social history, the patient's mother had "lived for her children" and was resentful when her sons married and left her. She had been especially fond of the patient and had given him privileges that his brothers did not share. His father, on the other hand, was a severe disciplinarian and "overreligious." The patient had to leave school to go to work at the age of 13 and obtained a job as an apprentice shipwright in a local shipyard. He was a good worker and later got a job as a wood caulker, first class, at the Charlestown Navy Yard. He held this job for 5 years and then secured work at the Brooklyn Navy Yard, where he worked for 3 years. At the end of that time he returned to Boston, was re-employed at the Charlestown Navy Yard and continued to work there for 4 years. At that time his jail record commenced, and since 1939 the patient had not worked.

Meanwhile, at the age of 21, he had married a girl several years his junior. This marriage was not a happy one from the beginning, and the couple separated within a year. At the age of 26 the patient married for the second time. This wife was 9 years older than he, had been previously married and had five children. There seems to have been a strong mother-son relation in this marriage, and the patient "relied and leaned on" his wife. There were four children by this marriage.

The patient was brought into the hospital by a court probation officer on February 16, 1943. He was shabby and

unkempt, stated repeatedly that he had dragged his wife and children down to the dregs and they would be better off without him, and seemed apprehensive about being hospitalized. He was, however, anxious to have help, since he was afraid he would again be sent to Bridgewater. He was admitted for a 2-week period of observation. At the end of that time, it was suggested that he return to his job on working parole and save money to pay for the conditioned-reflex treatment. (It is believed that assuming financial responsibility by the patient as early as possible is psychologically constructive.) After working a month under this arrangement, he expressed his amazement that he could pass beer parlors and other places where liquor was sold without being tempted to go in and have a drink. He worked out a budget with the social worker and began to save toward his conditioning treatment.

On May 3, the preliminary series of treatments was begun, and to date the patient has had four preventive reinforcement conditionings. A plan was worked out whereby he gradually spent more and more of his nights at home. He was given two raises in pay.

In view of the severity of his alcoholism, this patient remained as a boarder at the hospital for a full year. He still gets easily upset over small matters, but he is being exposed gradually to the tensions that he meets outside the hospital, so that he will learn to handle them without drinking. Considering his long period of drinking and his court record, it is extremely gratifying that he continues to be abstinent after a period of 9 months.

CASE 3. A 32-year-old Irish-American had been in the hospital four times previous to his last admission in January, 1943. He began drinking when he was 22 and continued until the age of 25, when he stopped. No clear history could be elicited concerning when he resumed drinking, but his first admission to the hospital was in October, 1937. He came in again in March, 1938, in May, 1942, and in November, 1942. His attitude on each of these admissions was hostile and suspicious, and he stated that drinking was not a problem for him, since he did not drink to excess. On his fifth admission in January, 1943, however, he was more co-operative and the following social history was elicited.

The patient left school after 3 years of high school and went to work for a gasoline concern, with which he stayed for 10 years. Business later became dull and about 3 years previous to admission he got a job retreading tires. His father died when he was 10 years old and his eldest brother, who was 20 years older, seems to have taken the father's place. The patient was his mother's favorite child, and after he married at the age of 23 the mother lived with his wife and himself. His married life was harmonious until 3 or 4 years ago, when his wife's mother came to live with them. Both she and her daughter drank and arguments ensued about this, since the patient did not like to have drinking in the home. He decided that it was right for him to drink if they did, and it was shortly after this that he was admitted to the hospital for the first time. Finally he left home and took a room. Because of loneliness and worry about his child, he continued to drink. Fear that the child might be put in a "home" seemed to bring about a change in his attitude, for on his final admission he was anxious for treatment.

It was arranged that the patient should stay at the hospital on working parole, meeting his board out of his pay and saving money for the conditioned-reflex treatment. To date he has been working regularly and is entirely abstinent.

It has been found that such a protective environment should be continued for about a year, supplemented, as mentioned above, by conditioned-reflex treatment, psychotherapy, social adjustments and, if necessary, relaxation therapy. The resources of this hospital are limited. It is located in a tavern and package-store district; comfortable living quarters and adequate grounds for outdoor activities are lacking; no skillful and enthusiastic recreational therapists are available to schedule and organize the patients' free time in a pleasant way. If, in spite of all these drawbacks, constructive and

encouraging work has been accomplished, how much more could be done under more favorable conditions! With adequate grounds and resources, for instance, workshops might be set up where patients could engage in such work as carpentry, cabinetmaking, soldering and repairing mattresses, for which they would be paid a regular salary. In this way, many patients could be salvaged who had not yet reached a point in their rehabilitation where they could safely be allowed to take employment outside the hospital but would work well and efficiently if adequately safeguarded. Such patients, moreover, could be kept under treatment for an indefinite period of time, meanwhile learning a trade or becoming more adept at their own trade. When finally discharged, they would emerge from the hospital better equipped physically, mentally and economically to carry on.

Such a plan would be far superior to the present practice of sentencing an alcoholic patient to a state farm, where he works under compulsion. In sentencing a man to labor, no attempt is made to win his co-operation through an appeal to the more mature and ethical components of his personality. Such compulsory treatment of a sick person —

which an alcoholic patient really is — is likely to elicit feelings of hostility, which prevent any good effects from being achieved. In the plan outlined above, on the other hand, the patient would work on a purely voluntary basis. He would be treated as a mature, intelligent person, capable of co-operating in the plans for his rehabilitation, and his interest in helping himself would be encouraged and developed. This approach is the very keystone of successful treatment, for unless the patient's full co-operation has first been secured, the other steps in the plan of therapy — conditioned-reflex therapy, psychotherapy and social readjustments — cannot be effective.

SUMMARY

The role of a part-time protective environment with working parole (in contrast to full-time confinement) as an adjuvant to conditioned-reflex treatment and psychotherapy is discussed. According to the experience at the Washingtonian Hospital, this threefold plan represents the most promising and well-organized treatment for alcoholic patients.

41 Waltham Street

EPIDEMIC KERATOCONJUNCTIVITIS*

Report of a Case with Marked Systemic Manifestations

JOHN J. CURRY, M.D.,† AND FRANCIS C. LOWELL, M.D.‡

BOSTON

THE clinical features of epidemic keratoconjunctivitis have been well described by Hogan and Crawford¹ and more recently by Sanders and his co-workers.² According to these authors, at the onset there was usually unilateral hyperemia and swelling of the palpebral conjunctivas and "a sandy feeling" in the eye. This was associated with lacrimation, but only rarely was there a purulent discharge. After twelve to thirty-six hours the bulbar conjunctiva also became congested and hyperemic. Edema of the lids was often present in varying degrees. In a few cases pseudomembranes appeared, usually on the conjunctiva of the lower lid. Corneal infiltration appeared in 52 per cent of Sanders's series of 80 cases, and in 33 per cent of these was associated with 5 to 15 per cent impairment of vision. In 42 per cent of the series the other eye became involved after varying periods of time. Swelling of the preauricular glands was found in 93 per cent of the cases, and considerable significance was attached to this finding.

Among the systemic manifestations headache was by far the most frequent, appearing in 61 per cent of the cases. As a rule it was moderately severe and not relieved by analgesics. Fever and malaise were also noted.

It appeared that trauma or inflammation might predispose the eye to an attack of epidemic keratoconjunctivitis. The possibility of transmission by means of instruments and solutions used in eye examinations in the New York epidemic was also mentioned.

The sequence of appearance of the objective signs and their intensity varied greatly in the cases studied. The initial symptoms had no bearing on the duration or severity of the disease.

The following case is reported because it had many of the features of epidemic keratoconjunctivitis in association with prominent systemic manifestations. An opportunity was afforded for hospital study, which revealed the presence of abnormal lymphocytes in the blood, with a marked fall in polymorphonuclear cells during convalescence, a palpable spleen and a normal spinal fluid. Antibody for the virus of epidemic keratoconjunctivitis appeared in the serum after recovery.

*From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

†Instructor in medicine, Boston University School of Medicine; chief resident, Evans Memorial, Massachusetts Memorial Hospitals.

‡Assistant professor of medicine, Boston University School of Medicine; member of staff, Evans Memorial, Massachusetts Memorial Hospitals.

CASE REPORT

W.M., a 27-year-old, married metal worker, was admitted to the Massachusetts Memorial Hospitals on February 4, 1943, because of severe frontal and occipital headache associated with fever of 5 days' duration. He had previously been well except for a mild respiratory infection that cleared completely 14 days before the onset of the present illness. One week before admission he had a chilly sensation followed by fever, which subsided by evening. Fever recurred the following morning, and at that time he noted swelling about his eyes, which became quite painful. Lacrimation was profuse. The lymph nodes in the region of the ears were enlarged and tender. Frontal and occipital headaches appeared and quickly became severe. Salicylates failed to give relief. With an increase in fever, sulfathiazole was given in therapeutic amounts. This produced no change in the patient's condition, and the drug was discontinued after 3 days.

The red-cell count was 4,500,000 and the hemoglobin 12.5 gm. per 100 cc. The white-cell count was 6800, with 76 per cent neutrophils, 18 per cent lymphocytes, some of which were atypical, 5 per cent monocytes and 1 per cent eosinophils. The urine was normal on several examinations. The Hinton test on the blood serum gave a negative reaction. The blood nonprotein nitrogen was 21 mg. per 100 cc., and the fasting blood sugar 81 mg. The total protein of the blood was 6.09 gm. per 100 cc., with the albumin and globulin fraction 2.63 and 3.46 gm., respectively. Several cultures of the throat, eyes and blood failed to show any pathogenic organisms. Repeated agglutination tests on the blood serum for typhoid, paratyphoid, typhus and undulant fevers and dysentery were negative. The blood sulfathiazole level was zero.

The course in the hospital is shown in Figure 1, in which the major features of the illness are correlated. Shortly after entry the patient was placed in a darkened room and strictly

FIGURE 1. Chart Showing Clinical Data.

At that time the temperature was 103.5°F. The following morning he was referred to the hospital for treatment.

The patient stated that he had had foreign bodies in his eyes on several occasions, since his work entailed frequent grinding of metals, the most recent occurrence of this kind having been 2 months before the present illness. One week prior to its onset a fellow employee had a "sore eye" due to a foreign body. In common with other employees the patient had been working longer hours than usual and under increased tension.

On admission the rectal temperature was 101.8°F., the pulse 100, the respirations 20, and the blood pressure 122/80.

The patient was well developed and well nourished. Lethargy was pronounced. There were several evanescent zones of erythema scattered over the face and forearms. Periorbital edema was moderate, but especially pronounced in the upper lids, particularly on the right. The conjunctivas were diffusely injected. There were no follicles, hemorrhages or pseudomembranes. Photophobia was marked and lacrimation was profuse. There was no purulent discharge. Vision on gross tests was unimpaired. The cornea and fundi were normal, and no evidence of keratitis was found. The oral mucous membranes were hyperemic, with several herpetic lesions on the anterior fauces and palate. There were enlarged, tender lymph nodes in the preauricular, occipital and cervical regions and in the right axilla, and there were nontender nodes in both inguinal regions. No other lymph nodes were palpable, and the neck was not stiff. The heart and lungs were normal and the abdomen was soft. The liver and spleen were not palpable. There was no edema except that noted in the orbital regions. Neurologic examination was normal except for the presence of slightly increased bilateral reflexes.

isolated. On the 1st and 2nd days he voided large amounts of urine at infrequent intervals. During that time the erythema of the skin and the herpetic lesions in the oral cavity disappeared. For the first 4 days there was a gradual fall in temperature and the headache decreased, but lethargy, periorbital edema and conjunctivitis persisted. Treatment was symptomatic. Cold boric compresses were applied to the eyes, and codeine and aspirin were given for the headache.

X-ray examination of the chest on the 2nd day revealed perihilar and peribronchial infiltration, and little change was noted when the examination was repeated on the 7th day. By the 5th day the headache had disappeared, but because of persistent depression a lumbar puncture was done. It yielded a clear colorless fluid. The initial pressure was 165 mm. of water, the dynamics were normal, and there were 4 lymphocytes per cubic millimeter. The total protein was 51 mg. per 100 cc., the sugar 80 mg., and the chloride 691 mg. A Wassermann test and colloidal-gold test were negative. The next day the temperature was normal and the spleen became palpable for the first time. The corrected sedimentation rate was 0.7 mm. per minute. The heterophile agglutination test with a dilution of 1:64 was faintly positive. X-ray films of the skull and a flat plate of the abdomen were negative. On the 9th hospital day the patient was allowed up, and 3 days later he left the hospital.

During the hospital stay and following discharge samples of blood serum were collected for antibody determinations (Fig. 1). No antibody was demonstrated during the acute phase of the illness.* A significant titer of antibody was present in the specimen taken 2 months after discharge. No antibody against the Eastern and Western strains of equine

*We are indebted to Dr. Murray Sanders for the antibody determinations, which were carried out in his laboratory at Columbia University.

encephalomyelitis was found. In view of the herpetic lesions on the roof of the mouth, noted on admission, it is perhaps unfortunate that tests for antibody against the herpes virus were not carried out. The clinical course and the short duration of these lesions do not, however, lend support to the view that the herpes virus played a dominant role in the patient's illness.

COMMENT

The diagnosis of epidemic keratoconjunctivitis is easily made in the presence of an epidemic and when conjunctivitis and periorbital edema on one or both sides, enlargement and tenderness of the preauricular lymph nodes and keratitis are found. When keratitis is absent, as it is in 47 per cent of the cases,² and the disease is sporadic, the diagnosis is difficult unless the virus of epidemic keratoconjunctivitis is isolated or a rise and fall in antibody titer is demonstrated after the acute phase of the illness.³

In the present case, keratitis was absent and isolation of the virus was not attempted. Antibody in low titer did, however, make its appearance after recovery, which gives support to the clinical impression of epidemic keratoconjunctivitis. The possibility cannot be ruled out that the patient had some other virus infection that was followed by an antibody response demonstrable by the technic used.

Trichinosis and acute glomerulonephritis were considered on entry, but nothing in the clinical course supported these diagnoses. The presence of atypical lymphocytes and a palpable spleen suggested infectious mononucleosis, but the atypical cells were not the type usually seen in this disease, and furthermore the heterophile agglutination test seven days after admission—fourteen days after onset of the illness—was only faintly positive in a dilution of 1:64, a result that is considered to be within normal limits.

The history of exposure to a fellow employee who had a "sore eye" one week before the onset of the patient's illness is of interest because it coincides

with the probable incubation period of epidemic keratoconjunctivitis which is believed to be seven to ten days.

The marked depression with only mild ocular disease is unusual. Two cases were noted in the Schenectady epidemic.⁴ One case showed persistent marked sleepiness, and in both cases severe emotional disturbances were present. As shown by Figure 1, the depression was not only severer than the ocular disease but also cleared less rapidly.

The rise in antibody was unusually delayed. No antibody was demonstrated in the blood obtained one month after recovery. One month later, however, a titer of 100 neutralizing doses was present. Four months after recovery this had fallen to 10 neutralizing doses. In the studies reported by Sanders and Alexander³ the antibody titers in the blood of patients recovering from epidemic keratoconjunctivitis varied between 100 and 10,000 neutralizing doses, and in a few cases the titer has been even higher.⁵

SUMMARY

A case is presented that showed many of the signs and symptoms of epidemic keratoconjunctivitis.

The outstanding feature was the presence of severe depression with only mild ocular disease.

Serologic studies during convalescence showed the development of antibody against the virus of epidemic keratoconjunctivitis.

MEDICAL PROGRESS

THE PHYSIOLOGIC SIGNIFICANCE OF VITAMIN C IN MAN*

LIEUTENANT MICHEL PIJOAN (MC), U.S.N.R., AND
LIEUTENANT-COMMANDER EUGENE L. LOZNER (MC), U.S.N.R.

BETHESDA, MARYLAND

FOR hundreds of years seafaring men experienced the ravages of scurvy. At the time of Columbus, scurvy was one of the most prevalent diseases of Europe. In fact, many observers thought that most diseases could be considered as outgrowths of scurvy. The medical literature is vague in reporting the first cases, but the disease was known as a most serious affliction among the Crusaders. Toward the end of the fifteenth century, Vasco da Gama reported that on his voyage around the Cape of Good Hope scurvy took by death nearly two thirds of his crew. In 1535, Cartier in Canada lost a quarter of his men by scurvy and the rest were rendered somewhat incapable by it. From the natives it was learned that decoctions from leaves and twigs served to cure or ameliorate the disease. Captain Cook and his men, on the other hand, escaped scurvy, as he reports, by provisioning their ships with fresh fruits from each shore they visited. The important feature of most naval medicine in the eighteenth century was the subject of scurvy, and in 1785 Sir Gilbert Blaine recommended lime juice in his *Observations on the Diseases of Seamen*, and thus the sailors were shortly nicknamed "limies." In 1841, Budd explicitly ascribed the antiscorbutic property of certain foods to a "definite substance," which, he wrote, "it is hardly too sanguine to state, will be discovered by organic chemistry or by the experiments of physiologists in a not too distant future." Some ninety years later his prediction was fulfilled. Thus today it is not strange that the problems of scurvy and the vitamin specifically involved in preventing this disease should receive attention.

Within the last ten years a voluminous literature has accumulated on sundry subjects containing the words "ascorbic acid" as the only common denominator. In fact, the current rate for such publications in the *Index Medicus* exceeds three hundred annually. Two forces appear to be responsible for the ascorbic acid miscellanea: first, the isolation and synthesis of the vitamin, and second, the development of methods for its assay. Despite the care and the delicacy required by the latter analytical procedures, they have been responsible for more than 75 per cent of the current literature

on this subject. A study of this stream of publications reveals, furthermore, that with no conceivable regard to any relation to the scorbutic process, vitamin C and its laboratory evaluation have been employed in almost every phase of normal and diseased body economy.

During the last three years, Butler andushman,^{1,2} Crandon, Lund and Dill³ and Rietschel and Mensching⁴ have contributed critical investigations on ascorbic acid deficiency. In the light of their investigations, the present communication reviews the function of ascorbic acid in body economy and presents additional observations bearing on the laboratory evaluation of vitamin C deficiency and on the human requirements of this acid. Two theses will be proposed and examined: that the only known lesion caused by vitamin C deficiency is the scorbutic process⁵; and that the evaluation of ascorbic acid deficiency in any given person from an assay of his usual diet is untrustworthy.

From the first proposition, it follows that ascorbic acid — whether synthetic or derived from food — has but two known uses, the prevention and the treatment of scurvy. The possible exception of its action in the intermediary metabolism of aromatic amino acids in premature infants^{6,7} is interesting and requires further investigation. Any other use of the vitamin in man lacks controlled experimental justification.

As regards the second proposition, not until a diet can be shown to produce a steady linear decline in the vitamin C content of the white cell-platelet layer or whole blood or to produce scurvy is one justified in calling the diet deficient. Inasmuch as scurvy can be anticipated only when the cellular elements of the blood become depleted of vitamin C, the level in cell-free plasma becomes an unreliable index. The ability to maintain a fixed level of vitamin C in the plasma, no matter how small, indicates for the person concerned a positive ascorbic acid economy.

ASCORBIC ACID

The discovery in 1907 by Holst^{8,9} that guinea pigs developed a deficiency disease distinct from polyneuritis and similar to human scurvy soon aroused the interest of chemists. Inasmuch as for centuries citrus fruits had been known as prophylactic and therapeutic agents against scurvy, the

newer studies began with concentration and isolation experiments, using lemon juice. The lack of stability of the vitamin hampered its immediate isolation, but a few properties of the antiscorbutic agent were recognized, including the fact that the active principle is destroyed by oxygen and tends to be more stable in acid solutions.¹⁰ Furthermore, it was observed that all biologic fluids capable of antiscorbutic action possess the common property of reducing a number of reagents.¹¹ On this basis, chemical methods were attempted to assay the antiscorbutic quality of foods. In the main, the early methods proved unsatisfactory. In 1930, it was found that the redox dye,^{3,7} dichlorobenzene indophenol, is particularly sensitive to reduction by some substance (reductone) having antiscorbutic properties.¹² In fact, there appeared to be a direct relation between the antiscorbutic property of a biologic fluid and its ability to reduce the redox dye. Final proof of this relation had to await the isolation of the vitamin and the eventual critical tests to which an assay must inevitably be subjected.

Following the isolation of the vitamin by King and Waugh^{13, 14} in 1932 and its identification with Szent-Györgyi's hexuronic acid,^{15, 16} it was soon synthesized from precursors having no antiscorbutic properties.¹⁷⁻¹⁹ The synthetic vitamin proved to be specifically antiscorbutic and reduced the redox dye, 2,6-dichlorobenzene indophenol, in equivalent molar concentrations. Thus, the claim for the dye method of assay, except in its complication by other reducing and interfering substances, was substantiated. It was shown, furthermore, that the levorotatory form, and not the dextrorotatory form, is antiscorbutic. The vitamin when in solution was unstable, — a finding previously noted concerning antiscorbutic biologic fluids, — oxidation being responsible for this instability.

Crystallographic and x-ray measurements of crystallized ascorbic acid (molecular weight 176) show that the molecule is flat.²⁰ It is soluble in water (1 gm. dissolves in 3 cc.), less soluble in alcohol (1 gm. dissolves in 50 cc.) and insoluble in benzene, ether, chloroform and fats. Since it is relatively unstable, such catalysts as traces of silver, copper and light — especially in the presence of riboflavin²¹ — must be avoided. The oxidation potential (E_0) of ascorbic acid at pH 4 at 35°C. is 0.166 V.²² In solution, vitamin C exhibits acidic properties, having a pK_1 of 4.17 and a pK_2 of 11.57. It has a typical ultraviolet absorption spectrum with a maximum at 265 μ . When ascorbic acid reacts with the redox dye, 2,6-dichlorobenzene indophenol (molecular weight 290), two enolic hydrogens of the ascorbic acid molecule reduce 1 molecule of dye. In the assay of the vitamin in biologic fluids the errors due to interfering substances, turbidity, extraneous pigments and oxidation can in the main be circumvented by special technic,²³⁻²⁶ and it is these techniques that are recom-

mended. A recently introduced method²⁷ shows considerable promise. By this method the ascorbic acid present is converted to dehydroascorbic acid, and on treatment with 2,4-dinitrophenylhydrazine an osazone is formed. In fact, it appears to be more trustworthy than the method using redox dye for whole-blood or tissue assays,²⁸ since hemochromogens and RSH compounds interfere with the accuracy of the redox system. In foods the phenylhydrazine method of assay requires considerable care, since osazones may form from substances other than ascorbic acid.

Recently the photochemical method for the determination of ascorbate with methylene blue has been applied and has been found more accurate and specific for small samples of blood than the commonly used dichlorobenzene redox.²⁹ In fact, this method makes the accurate assay of the vitamin C in 0.2 cc. of capillary blood an acceptable clinical procedure.

Although chemical and to some extent physical methods are replacing the biologic method of assay, the latter retains its place as the ultimate and definitional method of determining antiscorbutic activity. The biologic procedure, using guinea pigs, has been well established.^{30, 31}

THE SCORBUTIC PROCESS

The prolonged lack of sufficient ascorbic acid in the dietary produces in man, primates and guinea pigs a condition known as scurvy. It is assumed with good evidence that the other animals must be capable of synthesizing a part of or all of their requirements,³² since ascorbic acid is found in about the same proportion in their tissues. Furthermore, these other animals fail to exhibit the scorbutic process. At no time during the life cycle of man, however, is it known that synthesis of ascorbic acid takes place.³²

The scorbutic process is dependent on the depletion of ascorbic acid in animal tissues and the resultant morphologic change in the intercellular substance of certain mesenchymal derivatives.³³

In the scorbutic animal the ground substance, and fibroblasts are present as in the healthy animal, but collagen is not formed.³³ When the defective animal is given ascorbic acid, however, the condition is corrected and translucent bundles of collagen quickly appear.³⁴ The exact mechanism by which ascorbic acid effects this dramatic change is not known. The intercellular substance of bone (osteoid tissue) and of teeth (dentine) may be similarly affected by withdrawing or administering ascorbic acid. In scurvy all tissues lose collagen. Just where the weakness occurs in blood vessels is not known. Whether it develops in the sheath or in the endothelial cement substance, the fact remains that the vessels become more fragile and rupture easily on application of trauma or even do so spontaneously. As a result, hemorrhages occur, there is a fragmen-

tation of muscle fibers, and an intense reparative effort is apparent by the striking multiplication of sarcolemma. The gums, lacking cement substance, become boggy and swollen; infections may occur that often develop into pyorrhea. The more the gums are traumatized by chewing and so forth, the more serious this manifestation becomes.

Thus it is seen that stress modifies and to some degree determines the site of the gross lesions. The pressure of boots, the rubbing of trousers,³⁵ the location of vessels near a bony prominence and so forth are of considerable importance in explaining the distribution of the lesions. Blacksmiths and carpenters in times past developed lesions in their shoulders and arms; soldiers, in the calf and lumbosacral muscles.³⁶ Petechial hemorrhages of the eyelids are not uncommon in this disease, and perifollicular hemorrhages are an early sign. Lesions are further modified by growth. For instance, in infants bone changes are most striking, but in adults they are almost entirely lacking. In the latter, however, the dentine undergoes fairly rapid resorption and porosis.

Multiple periosteal hematomas become less and less frequent as the age of the patient increases; it is in the young and growing animal that bone pains chiefly occur. Hemorrhages in the muscles and joints may play a considerable role in the production of such pains. Other lesions include blood-stained effusions into the body cavities, which may give rise to bloody diarrhea. Lesions may at times be complicated by other diseases.³⁷⁻³⁹

Enlargement of the heart has been noted in a few cases of scurvy, and circulatory collapse has been described. Thiamine deficiency may contribute to such changes.

Clinically the scorbutic manifestations are often mixed with other nutritional deficiencies and the picture may be somewhat modified. Aside from other vitamin deficiencies superimposed on scurvy, prominent is the anemia that is often associated with it. Much has been written relating this anemia to a specific hemopoietic need for vitamin C.⁴⁰ Recent work, however, tends to disprove this, and the anemia seems to be frequently related to blood loss and to be relieved by iron therapy alone.⁴¹

PHYSIOLOGIC RELATIONS

The established role of ascorbic acid in animal tissues lies in its relation to intercellular material. In this relation the vitamin participates indirectly in calcium metabolism. Thus, in scurvy the osteoblasts, unable to form osteoid tissue, revert to a prototype and attempt to form a fibrous union between diaphysis and epiphysis.⁴² The chemical mechanism by which this vitamin induces the formation of collagen is unknown.

Many investigations have been presented in an endeavor to determine the subtle mechanisms of the

action of vitamin C. These investigations are in the main fortuitous observations in vitro and have little or no significance in vivo. For instance, it is known that ascorbic acid and dehydroascorbic acid and a number of their cation complexes (Fe^{++} , Cu^{++} and Mn^{++}) exert an effect on specific enzymes, such as cathepsin, papain, amylase and urease.²¹ The results from different laboratories are not in agreement, and it is probable that the conditions of experiments were not similar.

The catalyst found in many plant tissues capable of oxidizing ascorbic acid to dehydroascorbic acid and called "ascorbic acid oxidase" is a protein-copper complex.⁴³ Since there is evidence that the enzyme is not specific for ascorbic acid as a substrate, the above name should be used only in a restricted sense. In animal tissues, on the other hand, cytochrome-indophenol oxidase acts as the catalyst.⁴⁴ Hemochromogens likewise have a direct effect on ascorbic acid. It should be borne in mind that the role of all these mechanisms in the living animal is unknown.

The theory that ascorbic acid acts as a hydrogen transport or a respiratory catalyst in relation to animal tissues is unacceptable because there is no clear-cut evidence supporting this view.⁴⁵ Tissues depleted of ascorbic acid do not show a decreased respiration capacity, and when ascorbate is added to the depleted tissues, there is no rise in true oxygen consumption.

Recent unconfirmed reports suggest that ascorbic acid acts as an inhibitor in the adrenalin-adrenochrome oxidation in heart tissue.²¹ The effect of ascorbic acid and guinea-pig complement is interesting but has not been demonstrated conclusively in man. Thus, to date the chief role of ascorbic acid in human beings remains that of maintaining sufficient intercellular substance, and the lack of it results in the scorbutic process.

VITAMIN C DEFICIENCY AND ITS RELATION TO HUMAN REQUIREMENTS

Fundamentally, in the light of the foregoing, the amount of ascorbic acid needed in the body is that required to prevent scurvy. During recent years a great deal has been written with reference to the ascorbic acid status of normal and diseased persons. In the main, these investigations fall into three groups: those that deal with plasma levels of ascorbic acid as a reflection of the dietary intake, those that deal with plasma levels as a reflection of the tissue content of the vitamin and those that deal with ascorbic acid in terms of body saturation. By these methods a galaxy of nonscorbutic conditions have been studied. Such terms as "a relative insufficiency" of ascorbic acid, "subclinical scurvy" and the ascorbic acid required for "optimum health" are essentially undefined; the use of the term "latent scurvy" as a clinical entity described by Hess⁴⁶ is probably acceptable.

Significance of Blood Levels of Ascorbic Acid

The question of the meaning of blood values has recently been answered almost completely by a direct and well-planned experiment. Crandon³ conceived the idea of inducing scurvy by placing himself on a vitamin C-free diet and studying the changes that occurred in the process. His ascorbic acid plasma level dropped to zero within forty-one days and remained there for a period of thirteen weeks before the signs of scurvy appeared. On the other hand, the white cell-platelet layer fell to zero just prior to the advent of the first signs of scurvy.

Butler and Cushman^{1,2} had already observed that the ascorbic acid content of the white cell-platelet layer of centrifuged blood is probably the most accurate indicator of prescorbutic status. These investigators found that this level may be well within normal limits (25 to 38 mg. per 100 gm.), in spite of a very low plasma level. These cells apparently represent actual tissue stores of this vitamin. Thus, low plasma values do not necessarily indicate a scorbutic process unless such values exist concomitantly with a deficiency of the white cell-platelet content.

It appears from these studies that a fixed plasma value, no matter how low provided some is present, indicates a positive ascorbic acid economy. A continued drop in the plasma values and, of even greater importance, that in the white cell-platelet values indicate a shortage of the vitamin in the dietary.

There is no clinical justification for the idea that a plasma level above 0.7 mg. per 100 cc. is necessary for optimum health.⁴⁷⁻⁴⁹ One of us (M. P.⁵⁰), when studying a group of Indians whose dietary pattern was fairly rigid both in summer and winter seasons, assumed that a low plasma value implies an insufficiency of ascorbic acid. In spite of the fact that during winter months the daily intake of ascorbic acid failed to exceed 15 mg., no case of frank clinical scurvy could be found. It was believed, however, that probably a mild scurvy existed, a misconception that is now acknowledged. In a later study of early Spanish-American settlers stigmas of scurvy on dietaries never exceeding 25 mg. of ascorbic acid daily could not be ascertained.⁵¹ It was thought that for some obscure reason that had eluded most investigators, a continued low intake of ascorbic acid did not produce symptoms of frank scurvy. Thus, in the light of these studies there is no reason to presume, as some have indicated,⁵² that a level of 0.5 mg. per 100 cc. or less is diagnostic of scurvy. Ingalls⁵³ pointed out some time ago that in scurvy the plasma ascorbic acid values are always zero or a titratable trace within the error of the method. Crandon, Lund and Dill³ clearly demonstrated that a plasma level of zero content, provided that the white cell-platelet vitamin content is sufficient, produces no untoward physiologic effects.

The findings of Rietschel and Mensching⁴ are entirely confirmatory. They placed a normal man on a vitamin C-free diet for one hundred days. The plasma level and urinary excretion fell to zero, but no evidence of scurvy, capillary fragility or physiologic defect and no clinical symptoms appeared. It is only when the white cell-platelet layer falls significantly that certain symptoms manifest themselves and scurvy is expected.^{1,2} Crandon's experiment showed that the white cell-platelet level of ascorbic acid is the last to be depleted in experimental scurvy and the first to reach its peak following therapy.

The whole-blood value, indicating a combination of what exists in the plasma, the red cells and particularly the white cell-platelet layer, is also a better index than is the level in cell-free plasma,^{1,2} and falls gradually on a scorbutic diet until such time as the traces of ascorbic acid in the white cells and platelets are sufficiently low to be unmeasurable when diluted by the plasma and red cells.

In summarizing the blood values of ascorbic acid, it can be said that a steady depletion or continued lowering of the plasma value and subsequently the white cell-platelet layer indicates a dietary shortage, and that when the white cell-platelet layer levels become completely depleted scurvy follows.

It should be emphasized that the diagnosis of scurvy without clinical signs, solely on the basis of laboratory procedures, can never be justified. On the other hand, a prescorbutic state based on depleted white cell-platelet values as an index is warranted because it is during this period that Crandon noted fatigue and weakness as well as certain other changes.

Since Crandon's experiment, one of us (M.P.) has maintained a plasma value of 0.0 to 0.2 mg. of ascorbic acid per 100 cc. of plasma with no untoward signs of symptoms (see the section on wound healing below). This has lasted for twenty months, and the white cell-platelet value has been remarkably constant at 26 ± 2 mg. per 100 gm. of cells. At no time has there been evidence of any urinary excretion of ascorbic acid.

It appears at once from the above that what is important in the evaluation of the ascorbic acid status is the tissue ascorbic acid value, which is best represented for test by a whole-blood or a white cell-platelet determination. It may be conjectured that the plasma level indicates essentially an overflow or a phase of positive balance, and that when this becomes high enough urinary excretion takes place.⁵⁴

Unlike many of the other vitamins in man, ascorbic acid requires a constant intake to maintain a fixed tissue level. If one is well supplied with vitamin C (presumable saturation), he may be able to go for many months without the vitamin until the continued linear decline in the tissues reaches

zero. On the other hand, certain maintenance doses protect from scurvy.⁵¹ At present there is no clear-cut way of determining whether body economy is more effective under saturation or under unsaturation while a positive balance is maintained. Nevertheless, it must be realized that 16 to 25 mg. of ascorbic acid daily protects the human subject against scurvy. The saturation test has little or no bearing on the subject of frank clinical scurvy.

In this regard it is interesting to note that although infants are extremely susceptible to scurvy, they fail to develop it on fresh cow's or mother's milk.⁴⁶ On the other hand, processed milk does not protect against scurvy.⁴⁶ With this in mind, reference is made to the careful observations made in 1915 by Still,⁵⁵ who showed that nearly 80 per cent of the cases of scurvy appeared between the ages of six and ten months and that the disease required from six to nine months to become manifest, depending on the degree of dietary deficiency. It is evident, therefore, that there must be a prolonged period of nutritional failure that precedes the diagnosis. It is apparent that different degrees of tissue saturation determine the time interval required for scurvy to manifest itself during a dietary deficiency. For instance, in the past it had been noted that among soldiers and sailors a certain number developed scurvy on a ration that did not harm others. These observations may be of importance during present times, when members of our armed forces may be given large doses of the vitamin — a total of 3 or 4 gm. over a few days — before undergoing missions during which the intake or source of vitamin C may be limited. On the whole, however, the general thesis remains that relatively small amounts of ascorbic acid are required in the dietary to prevent scurvy in man. In monkeys the requirements are sometimes greater, and the guinea pig in terms of body weight requires more ascorbic acid than does man.

Contrary to this point of view are the opinions of others. Intakes of ascorbic acid as high as 60 to 100 mg. or even more a day have been recommended.⁵⁶⁻⁵⁸ The reason for the high intake is based on saturation results, in which a high intake is required to maintain a daily excretion of ascorbic acid approximating the amount ingested. A high intake for a short period of time may be advantageous only when a dietary shortage is contemplated or anticipated.

Significance of Urinary-Excretion and Saturation Tests

In 1935, Abbasy, Harris, Ray and Marrack⁵⁹ introduced the determination of the twenty-four-hour urinary excretion of ascorbic acid as an index of the status of this vitamin. They assumed that a low excretion level indicated an insufficiency. It was soon found that this method was unsatis-

factory,⁶⁰ because of the wide variation in excretion and the poor correlation with plasma values.

The saturation test soon replaced the urinary-excretion test in the evaluation of ascorbic acid status. This involved the administration of fairly large doses of ascorbic acid and the assay of this vitamin in the urine. Johnson and Zilva⁶¹ believed that saturation of the tissues with vitamin C was reached when the quantity ingested approximated the daily excretion. Aside from the fact that other reducing substances may be present in the urine and the fact that the kidney reabsorbs about all the ascorbic acid excreted unless complete saturation is present, the test has numerous faults. First of all, Hawley, et al.⁶² report that the amount of ascorbic acid excreted in the urine may vary according to the acid-alkaline content of the diet, and others⁶³ have reported changes in urinary excretion following the administration of various preparations. Furthermore, on the basis of Crandon's³ experiment the assumption that saturation with the vitamin is necessary in optimum health has little or no evidence in its support. In view of the fact that any fixed value in the plasma indicates a state of positive ascorbic acid economy, the saturation test has no place either as a diagnostic test for scurvy or as a criterion for the therapeutic administration of ascorbic acid. On the other hand, plasma-tolerance ascorbic acid curves may show promise as criteria for evaluating the previous intake and the extent of tissue stores.⁶⁴

Other Objective Tests

The Göthlin,⁶⁵ Dalldorf⁶⁶ and Rumpel-Leede⁶⁷ tests for capillary resistance are equivocal, positive or negative, in scorbutic and many nonscorbutic persons, and as a consequence should not be considered as precise diagnostic criteria. The intradermal test, in which the redox dye, 2,6-dichlorobenzenone indophenol, is injected into the skin and the time for the disappearance of color is used as an index of the status of ascorbic acid, has also been proved valueless.⁶⁸

TREATMENT OF SCURVY

The treatment of scurvy consists in placing the patient in a clean environment, if possible on bed rest, and the giving of approximately 1 gm. of ascorbic acid daily for about ten days. Synthetic vitamin C is recommended for obtaining a high dosage. If the synthetic preparation is unavailable, high vitamin C-containing foods — citrus fruits, tomatoes and certain berries — may be used. The parenteral administration of ascorbic acid is rarely indicated, but it may be done, if circumstances require this procedure, either intravenously or intramuscularly.⁶⁹ The presence of infections or other lesions concomitant with scurvy must not be neglected. The patient should receive a diet high in nutritional value to improve his general status;

some physicians administer high doses of the other vitamins as well as ascorbic acid in the treatment of scurvy. Anemia, when present, usually improves spontaneously or with iron. Following treatment, the patient should be instructed to continue on an adequate nutritional regime.

RELATION OF OTHER CONDITIONS TO ASCORBIC ACID ECONOMY

A sizable volume would be required to review all the diseases in which the therapeutic use of ascorbic acid has been attempted. Most of the empiricism for the use of this vitamin in diseases other than scurvy is derived either from the findings of low plasma values or from tissue unsaturation. It is now known that such methods of determining the ascorbic acid status are untenable, and there is consequently little evidence supporting the therapeutic use of ascorbic acid in conditions other than scurvy.

Dental and Gingival Disease

Since one of the most frequent changes that occur in scurvy is a swelling of the gums with bleeding, it has been reasoned that pyorrhea may be due to an inadequate intake of ascorbic acid.⁷⁰ Although it is true that in scurvy a superimposed infection may take place between the teeth and gums, pyorrhea usually exists independently of clinical scurvy.⁷¹ Low plasma ascorbic acid values in many patients with pyorrhea brought about the misleading conception that this disease is induced primarily because of a supposed prescorbutic condition. Pyorrhea is a disease of the gums due to an infectious process producing exudate, with the formation of pockets in the dentogingival space. The treatment of this condition is a local one and involves systemic care only when some other disease contributes to the process. Thus, the use of vitamin C in gingival lesions has a highly questionable foundation unless scurvy is present.

Diseases of the Gastrointestinal Tract

It has been noted by Warren, Pijoan and Emery⁷² that patients on Sippy diets (low in ascorbic acid) being treated for duodenal ulcers have low plasma ascorbic acid values. Portnoy and Wilkinson⁷³ found in their series of ulcer patients that the plasma ascorbic acid values ranged from 0.14 to 0.59 mg. per 100 cc. Others emphatically claim that ulcer patients have a deficiency of ascorbic acid.⁷⁴ Although it is admitted that the Sippy diet contains only about 5 mg. of ascorbic acid per day during the first week and about 15 mg. per day during the fourth week, the low plasma value found in a single determination does not mean either scurvy or a tendency to it. If a series of plasma or blood values tends to decrease — as contrasted with fixed low plasma levels — on the Sippy regime, it can be assumed that the dietary is insufficient in main-

taining a positive ascorbic acid economy and that this vitamin is being withdrawn from the tissues. Two cases have been reported in which scurvy developed, as might be expected, on an extended period of a Sippy diet.⁶⁰ There is no evidence that ascorbic acid affects the bleeding of ulcers in non-scorbutic subjects.⁶⁰

Rheumatic Fever

That ascorbic acid deficiency may be an etiologic factor in rheumatic fever was suggested by Rinehart,⁷⁵ whose general conclusion was that this disease is caused by the combined effects of ascorbic acid deficiency and infection. This point of view has been challenged by many.⁶⁰ The low plasma level of ascorbic acid so often found in patients with rheumatic fever indicates only the possible need for a greater ascorbic acid intake in the dietary to maintain a fixed plasma value. The fact that a low plasma value does not indicate scurvy at once limits the relation as expressed by Rinehart. Recently Kuttner⁷⁶ reported that the addition of vitamin C, as well as of other vitamins, did not reduce the incidence or recurrences of rheumatic manifestations in children with rheumatic fever. So far as can be determined, clinical scurvy has never been observed in acute rheumatic fever.

Tuberculosis and Other Infections

Although the patient with active pulmonary tuberculosis does not develop scurvy on an adequate intake of ascorbic acid, he requires, for some peculiar reason, more ascorbic acid in his dietary to maintain a high fixed plasma value of 0.7 mg. per 100 cc. than does a normal person.⁷⁷ Low levels are easily maintained by such patients on a so-called "average intake." This situation is true in many other infections. There is no evidence, however, that deficiency of this vitamin plays a specific role in the susceptibility to infections in human subjects.

Wound Healing

Since it has been emphasized by Wolbach and Howe³³ that the fundamental lesion in scurvy is due to a lack of intercellular substance and poor capillary formation, interest was soon directed to the study of experimentally produced wounds in latently and frankly scorbutic guinea pigs.⁷⁸ Wounds of scorbutic guinea pigs healed slowly and with poor tensile strength. In fact, a relation has been established between the wound ascorbate value and its tensile strength in scorbutic and prescorbutic guinea pigs.⁷⁹ On the other hand, with the exception of Crandon's work,³ studies of wound healing in human subjects have not been sufficiently controlled. So far, the evidence that ascorbic acid is necessary for wound healing in the nonscorbutic subject has no foundation whatsoever. Crandon³ after three months of an ascorbic acid-free diet, with no plasma ascorbic acid for several months,

had perfectly normal wound healing as revealed by biopsies. It was only after he had developed clinical scurvy that wound healing was impaired. Since other reports in the literature indicate that low values of ascorbic acid may influence wound healing,⁸⁰ and since in such studies there were no human subjects as basic controls, one of us (M. P.⁸¹) made observations on a man who remained on a low vitamin C intake for twenty months. No foods containing significant quantities of ascorbic acid were consumed. A few well-cooked vegetables, whose acid content was negligible as determined by assays, were eaten from time to time. The dietary was as low in ascorbic acid as could be comfortably endured. The average intake averaged 16 mg. a day for twenty months, and at no time was it more than 25 mg. or less than 12 mg. The plasma ascorbic acid value remained for the most part at zero with occasional high increases, never exceeding 0.2 mg. The white cell-platelet layers, on the other hand, always exceeded 25 mg. per 100 gm. At the end of this period, while the patient was on the same diet, a wound was made in the left mid-back consisting of an incision 2.5 cm. in length and 1 cm. in depth into the subcutaneous tissue. Ten days afterward a biopsy revealed normal healing with ample intercellular substance and capillary formation.

It is thus evident that a daily dietary intake of ascorbic acid of between 12 and 25 mg. that maintained an extremely low plasma level but a value of 25 mg. or more per 100 gm. in the white cell-platelet layer was sufficient to produce adequate wound healing and collagen formation.

DIETARY FACTORS

Since it is our thesis that the amount of ascorbic acid required by the human subject is that sufficient to maintain an adequate tissue level, thus preventing scurvy, it is of interest to discuss briefly certain considerations relating to the foods that are rich in vitamin C.

Many reports have already appeared in the literature that deal with the ascorbic acid content of foods. Losses of the vitamin through processing have been studied by King and his associates.⁸²⁻⁸⁴ Their studies indicate that the loss of ascorbic acid is due to two essential factors: oxidation of ascorbic acid and the transfer of the vitamin to cooking fluids. Their assays and those of others stress the point that cooking may cause a considerable loss of the vitamin. Aside from this, there is a remarkable variation in the ascorbic acid content of a specific food. This may be due to a seasonal variation and to methods of storage. For instance, summer-grown tomatoes may contain as high as 25 mg. per 100 gm.,⁸⁵ whereas those purchased in April may average only 4 mg. per 100 gm.⁸⁶ Such variations are found to a greater or lesser degree in the majority of fruits and vegetables. Lately,

Pijoan and McCay⁸⁷ have collected sufficient data to show that values of ascorbic acid as expressed in standard food tables may be in error to the extent of 75 per cent and that the various methods of food preparation modify the content of ascorbic acid. There are many ways of minimizing the losses of this vitamin.⁸² There is, furthermore, the question of dehydroascorbic acid in foods. Chemically derived dehydroascorbic acid has been shown to be antiscorbutic, but it is somewhat questionable whether the dehydroascorbic acid in food is antiscorbutic. Nevertheless, one should assume for the present that until proved otherwise dehydroascorbic acid — no matter where found — protects against scurvy.

Because the cooking and processing of food effect a variable but at times considerable reduction in its antiscorbutic property, it is indeed fortunate that the daily requirements are not great.

* * *

The use of ascorbic acid, either synthetic or in the diet, is for the prevention or treatment of scurvy. With the possible exception of its influence on amino acid metabolism in premature infants, no other role can be ascribed to the vitamin.

A diet cannot be condemned as deficient in this vitamin unless a continued linear decline of the content of the vitamin in the whole blood, white cell-platelet layer or other tissue takes place, the appearance of scurvy being conclusive evidence.

Relatively small amounts of the vitamin — possibly 25 mg. or under a day — are necessary to maintain fixed blood or white cell-platelet levels. Any fixed level of the vitamin in the plasma, irrespective of how little is present, indicates a nonscorbutic process and a positive body economy.

EDITH E. PARRIS, *Assistant Editor*

CASE 30271

PRESENTATION OF CASE

A sixty-nine-year-old man was admitted to the hospital because of old draining sinuses of the back.

The patient had been in apparent good health until about one and a half years before entry, when he complained of pain in the back, which was diagnosed as right sacroiliac strain, and treated by brace and strapping. He continued to have pain in the back. About one year prior to admission he fell on the ice and shortly thereafter a slight swelling appeared in the midlumbar region. A few months later this suddenly ruptured, liberating a large quantity of clear fluid. This continued for three weeks, after which the character of draining material changed to pus, with considerable cheesy material intermingled with it. He entered a community hospital, where the draining area was incised and x-ray films were taken. His condition progressively became worse, however, and he was sent to this hospital. Some time during the year preceding hospital entry, he had noted a swelling in the right groin. No other information was available.

Physical examination showed a well-developed, somewhat cachectic man in no distress. He was quite confused. The heart was slightly enlarged. The lungs were clear. A large ovoid, nontender, elastic, nonfluctuant, noninflamed swelling was present in the right groin. In the lumbar region on the back there were three draining sinuses, from which mucopurulent material exuded. The entire skin of the spine was loose. No true points of tenderness were found.

The blood pressure was 166 systolic, 100 diastolic. The temperature was 101°F., the pulse 92, and the respirations 15.

Examination of the blood showed a white-cell count of 27,400, with 92 per cent neutrophils. The hemoglobin was 8.2 gm. per 100 cc. A Hinton test was negative. The urine was acid, with a specific gravity of 1.020 and a ++ test for albumin. The blood nonprotein nitrogen was 35 mg., and the protein 5.9 gm. per 100 cc.; the chloride was 97.6 milliequiv. per liter.

X-ray examination of the lumbosacral spine showed mottling, loss of bony detail and areas of

increased density and irregularity of both the upper and lower surfaces of the fifth lumbar vertebra. The right lumbosacral joint was also indistinct. The left sacroiliac joint was normal.

A culture of the pus from the sinuses gave a coagulase-positive, hemolytic *Staphylococcus aureus* and diphtheroids. Three smears showed gram-positive cocci in clumps. No acid-fast organisms were seen.

The patient was given several transfusions and intravenous fluids. On the third hospital day incision and drainage of the abscess in the right groin was carried out, with removal of 1000 cc. of thick greenish pus. The abscess seemed to extend retroperitoneally, but a lipiodol injection showed no connection with the draining sinuses in the back, with the fifth lumbar vertebra or with the right hip joint, although the dye passed down for a distance of 8 cm. on the anterior aspect of the leg. A culture of the abscess yielded a hemolytic *Staph. aureus* and diphtheroids. Cultures for fungi were negative.

The patient's condition improved slightly. The temperature ranged between 98.6 and 102°F. On the eighth hospital day he was given 3 gm. of sulfadiazine. For the next five days the temperature was below 101°F. On the thirteenth hospital day he had a sudden rise of temperature to 103°F., which fell after a few hours to 100°, with subsequent spiking to 103° for the next two days, when it again fell to about 100°. On the seventeenth hospital day an abscess in the left buttock was drained, giving 300 cc. of the same type of purulent material. Smears and cultures of the material again yielded a hemolytic *Staph. aureus* and diphtheroids. A blood culture was negative. Beginning on the eighteenth hospital day, he was daily given penicillin intramuscularly every four hours (a daily total of 135,000 units) and 2500 units locally for six days. The character of draining material became mucoid and decreased somewhat, and the temperature came down to normal. On the twenty-fourth hospital day, examination showed occasional rales in both lungs. The liver was enlarged and tender. X-ray films of the chest showed no gross consolidation; there were mottled areas of increased density in both upper lung fields, and a small area lateral to the right hilus.

He continued to receive transfusions and intravenous fluids. On the twenty-seventh hospital day, a 300-cc. hematoma was found in the right groin; this was removed, and the bleeding point, which appeared to be an artery, was ligated. The temperature again spiked to 102 and 103°F. On the twenty-ninth hospital day a left ischiorectal abscess was incised and drained, giving purulent fluid. On that day he was again placed on a similar dosage of penicillin for six days; it was then omitted for three days and resumed for another eight days. From the twenty-eighth until the fifty-fifth hospital day

*On leave of absence.

the temperature remained normal. Re-examination of the lumbar spine on the forty-fifth hospital day showed an increase in the area of destruction of the anterior lower surface of the fifth lumbar vertebra. Little change was seen in the anterosuperior margin of the sacrum. Because of the destruction of the fifth lumbar vertebra, the interspace was considerably widened anteriorly. No soft-tissue shadow was visible in this region either in the anteroposterior or the lateral view. The hip joints showed no change. During the period in which the temperature was normal and drainage decreased he continued to lose weight and no evidence of healing could be seen. On the fifty-fifth hospital day he suddenly had a chill and a rise of temperature to 104°F., and of pulse to 140.

Physical examination was the same as before. A urine examination showed many white cells. A urine culture gave abundant growth of colon and proteus bacilli and gram-positive cocci in chains were seen in a stained smear. A blood culture was negative. Culture of the draining sinuses in the back still yielded a hemolytic *Staph. aureus* and diphtheroids, as well as *Clostridium welchii* and a species of *Alcaligenes*. Culture of the groin gave a hemolytic staphylococcus and diphtheroids. The white-cell count was 14,200, with a hemoglobin of 11.8 gm. per 100 cc.

The patient was given intravenous fluids, blood transfusions and 4 gm. of sulfadiazine. He continued to receive sulfadiazine daily for the next twenty-eight days, the blood sulfadiazine level reaching 5.2 mg. per 100 cc. During that time the urine continued to show many white cells and gave a ++ or +++ test for albumin; the temperature spiked to 103°F. on one or two occasions, but most of the time the temperature was about 101°. Although drainage from the various sinuses decreased, no evidence of healing could be seen, and the patient failed to gain weight.

On the seventy-third hospital day, his face became puffy. This increased during the next two weeks. X-ray re-examination of the spine on the seventy-eighth hospital day showed no definite change in the appearance of the fifth lumbar vertebra and of the adjacent surface of the sacrum; there was possibly a little new bone formation about the anterior margin of the first sacral segment. The fourth lumbar interspace appeared to be a little narrowed, and the right lower margin of the fourth lumbar vertebra showed a small area of irregularity suggesting destruction. Sulfadiazine was stopped on the eighty-third hospital day, and he was given bladder irrigations without any change in the character of the urine. From the eighty-seventh to the ninety-first hospital day the temperature gradually rose from 100 to 104°F. On the eighty-ninth hospital day he developed nausea and vomited several times. The nonprotein nitrogen was 84 mg. per 100 cc.; the serum protein was 5.1 gm. per 100 cc., and

the urine was the same as before. A plain film of the abdomen showed considerable gas distributed through many loops of the small intestine, none of which appeared to be abnormally dilated. There was gas in the stomach, but little in the colon.

On the ninety-fourth hospital day he developed jaundice and became comatose. The serum bilirubin was 7.6 mg. per 100 cc. direct, and 9.5 mg. indirect. The jaundice increased, the nonprotein nitrogen rose to 96.5 mg. per 100 cc., and the patient died on the ninety-sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT N. NYE*: I am not sure what is the best way to discuss this case, but I am going to say that I believe this man had tuberculosis of the spine, in spite of the fact that he was sixty-nine years old, and discuss the high points in the course of his disease on that basis. Of course in any man of this age with pain in the back the first thing one should think of is neoplasm of some sort, particularly metastatic cancer. But from the course of the disease, I do not believe that cancer is probable.

The man had been sick for approximately one and a half years before he entered the hospital. Of course the onset noted in the history was following a fall on the ice; but I doubt if that had anything to do with the actual disease itself. The record says that after this fall he had a slight swelling in the mid-lumbar region and that a few months later this suddenly ruptured, liberating large amounts of clear fluid. That is difficult to explain, but one might question whether it was an accurate observation. Certainly if it was tuberculosis of the lumbar spine and there was abscess formation that had dissected out to the back, one would not expect the fluid to have been clear. On the other hand, the chances are that it would not have been frank pus. Possibly because of the fact that it was not frank pus, the note is made that the fluid was clear. I also doubt the large quantity, because I should not expect appreciable amounts to be extruded in this condition.

The discharge then became purulent; in other words, it was secondarily infected. The record says that there was considerable cheesy material intermingled with the pus and that some time during the period prior to admission the patient noticed swelling in the right groin. It is not unusual for a tuberculous abscess of the spine to dissect in various parts of the body, and in this man the abscess in the groin was probably due to dissection following the psoas muscle, which is one of the favorite places for dissection from the lower part of the spine.

When the patient entered the hospital he had apparently lost considerable weight; he had fever, an elevated pulse and normal respirations. As one

*Assistant pathologist, Boston City Hospital; assistant professor of bacteriology, Harvard Medical School.

would expect, the white-cell count was elevated, with a high percentage of neutrophils. The hemoglobin was quite low, but one must realize that the disease had been going on for some time and that the man had probably not received ideal care. It is interesting that he showed a ++ test for albumin on admission. Whether that means that the man had a benign nephrosclerosis or that the inflammatory process had gone on to produce changes in the kidneys is questionable. The nonprotein nitrogen of course was high normal. X-ray examination of the lumbosacral spine showed a destructive lesion. Is there anyone here to demonstrate the films?

DR. MILFORD SCHULZ: Here we see the destructive lesion involving the body of the last lumbar segment. The faces of the adjoining vertebra are surprisingly intact. This is curious for a tuberculous process, although that does not necessarily rule it out. The superior surface of the sacrum looks a little bit irregular, and on later examination the inferior aspect of the fourth segment is involved. I do not believe that we can help you much.

DR. NYE: Have you the x-ray films of the chest?

DR. SCHULZ: Yes, but there is nothing that is incriminating. The findings described must have been found on another examination of the chest.

DR. NYE: In other words you question whether there was evidence of a pulmonary lesion. Of course that might have been based on a fluoroscopic interpretation.

DR. SCHULZ: Either that or other films of the chest were available.

DR. NYE: The x-ray films of the chest are of little assistance. Of course there was a destructive process in the fourth and fifth lumbar vertebrae that also involved the sacrum, and we shall have to let it go at that.

Culture of pus from the sinuses yielded a coagulase-positive hemolytic *Staphylococcus aureus*. That, I believe, was a contaminant. Of course a coagulase-positive hemolytic *Staph. aureus* is usually a virulent organism, but at the same time it does not have to be the primary etiologic agent. It can be a secondary invader of sinuses due to tuberculosis or to some other type of chronic draining infection.

Three smears showed gram-positive cocci in clumps. In other words they were probably looking for one of the unusual organisms, such as an Actinomycetes, which I shall mention in the differential diagnosis; but it appears that no so-called "sulfur granules" or gram-positive filaments that might suggest the organism of actinomycosis were observed. Also, no acid-fast organisms were seen, which one would not necessarily expect in direct smears even if this were tuberculosis.

The abscess in the groin was drained, and one liter of thick, greenish pus was obtained. This cavity, when it was injected, showed no connection with the process in the vertebra, but that does not necessarily mean that it did not rise there. Culture of

that pus yielded the same organisms — staphylococcus and diphtheroids — as the culture from the draining sinuses, which is reasonably good evidence that they were the result of one and the same process. It also says that cultures for fungi were negative. In other words, they probably tried to isolate one of the blastomycotic organisms. These yeastlike fungi grow reasonably well on ordinary culture mediums, and the fact that they were not obtained is fair evidence that this was not the etiologic agent.

The patient then developed an abscess in the buttock, which was probably due to dissection from the same process. This also yielded a staphylococcus and diphtheroids. At about the same time, around the twenty-fourth hospital day, the liver was large and tender. One thing that I have learned in looking over two of these cases every week is that a large liver clinically does not necessarily mean a large liver pathologically. I am doubtful of the significance of this large liver, but there are signs of liver disease later, and this may have some significance, possibly an extension of the process to the liver. I cannot explain the tenderness.

The next point, of course, is that the x-ray film of the chest showed mottled areas of increased density, but as you have seen, the film appears to be essentially negative. A hematoma developed in the groin abscess, which has little significance since this was a destructive lesion and undoubtedly an artery was involved.

Under penicillin, the temperature came down to normal and stayed normal for two or three weeks. Probably some of the fever was due to the absorption of products from the secondary infection, which was massive, and the penicillin may well have controlled that. But in spite of the drop in temperature, he continued to lose weight, and there was no evidence of healing of the sinuses. At about that time the kidneys began to show signs of involvement. The patient had a chill. The urine sediment contained many white cells, and a culture showed colon and proteus bacilli; gram-positive organisms in chains were seen in a smear, but individual colonies could not be obtained because of the spreading colonies of the proteus bacillus. The fact that the organisms were different from the organisms recovered from the various abscesses suggests that this was not due to a pyemic infection of the kidney — something coming from the blood stream or possibly by direct extension from the abscess that was already present — but rather to an ascending infection caused by the colon bacillus, which probably indicates a developing pyelonephritis. Again, the blood culture was negative, and the cultures from the sinus in the back still yielded a staphylococcus and diphtheroids as well as the Welch bacillus and a species of *Alcaligenes*, neither of which is important. The Welch bacillus is a habitant of the normal stool and is apt to be found in secondarily infected wounds like this; in the absence of

symptoms of gas-bacillus infection it has no significance.

Two days before death the patient developed jaundice and became comatose; the bilirubin was 7.6 mg. direct, and 9.5 mg. indirect. I do not know what the significance of that is. In cases of sepsis one frequently gets so-called "septic jaundice." Kimmelstiel* has mentioned cases of this sort which at autopsy showed little if anything specific in the liver and in which the jaundice was probably due to some terminal toxic condition. I do not know whether this amount could be accounted for on that basis. Do you, Dr. Richardson?

DR. WYMAN RICHARDSON: I do not believe so. Most of it was determined by the direct method.

DR. NYE: If this is not tuberculosis, what other diseases should one consider in which there are draining sinuses that refuse to heal?

One should always think of actinomycosis, probably an actinomycotic lesion in the spine. It does occur, but is usually secondary to some other process elsewhere, either to pelvic actinomycosis or to peritoneal or abdominal infection following a ruptured appendix. Furthermore, it is said that the actinomycotic lesion of bone is usually around the bone rather than in the bone, and I take it that this destructive process involved the body of the vertebra. Another thing is that no sulfur granules were found and that a smear showed only gram-positive cocci.

Another possibility is a chronic blastomycotic infection. These are extremely rare, and I have never heard of one involving the spine. Again the organism should have been cultured from the pus.

Another possibility is a chronic osteomyelitis due to a pyogenic organism. The commonest ones are staphylococcus and streptococcus, and occasionally pneumococcus, the typhoid bacillus and certain other of the gram-negative enteric bacilli. The history, however, does not sound like what one would expect with a chronic pyogenic osteomyelitis. Furthermore, I believe that in cases of chronic osteomyelitis there is usually evidence in the x-ray films of new-bone formation, such as in a Brodie abscess, which was not present in this case.

Tertiary syphilis or gumma of the bone might occur. It certainly would be extremely unusual for it to have a course such as this. Also, a Hinton test was negative, although we have recently had two cases of gumma at the Boston City Hospital in which the Hinton test was negative.

This man probably had amyloid disease. He had had a chronic infection on the basis of tuberculosis with secondary infection over a period of at least a year, possibly longer. This might well have accounted for the development of pyelonephritis in the kidney, which is a frequent sequela of amyloid disease in the kidney. It may also have accounted

for the evidence of liver failure at the end, although again I cannot rule out entirely some infectious process.

I believe that this patient had tuberculosis of the spine, with abscess formation, secondary pyogenic infection and dissection and pyelonephritis, probably on the basis of amyloid disease of the kidneys; the liver at autopsy probably showed little if anything, except for the possibility of amyloid disease.

DR. RICHARDSON: I am guessing this patient had actinomycosis: first because it seems to me that he had an excessive amount of pus, second because we rarely find actinomycosis here in this hospital when we look for it, and third because we have been told that there have been three cases of actinomycosis here recently, two of which have been discussed at these conferences, and since these rare things always go in threes, perhaps this is the third case.

DR. EARLE M. CHAPMAN: I saw this patient only once. I shall read briefly from my note in the record at that time:

The long duration of his illness and the failure to respond to penicillin and, I presume, to sulfonamide therapy, suggest that this process is either tuberculous or saprophytic, and also that the patient has failed to develop antibody to the causative organism. . . . The outlook seems grim. I have little to offer, although it would be well to do a skin tuberculin test, a flat film of the abdomen for question of abscess about the liver, an x-ray film of the chest and a culture for typhoid organisms.

DR. FLETCHER H. COLBY: I saw this patient a good many times toward the end of his illness. At that time his face was very puffy, but he had been given large amounts of testosterone and I understood that the puffiness of the face could be attributed to that. He did not have generalized edema. I saw him simply because he was a terrific nursing problem. He had had no previous urinary symptoms, but at some period earlier he had developed an urgency of urination that amounted to incontinence, and could not avoid wetting the bedclothes, so he was put on constant drainage. His urine was always purulent. He had many reasons for having purulent urine — constant drainage and infection by the proteus bacillus and other organisms. It seemed quite probable that he had a severe cystitis or possibly a pericystitis, with some possibility, which we never investigated, of actual fistula between the bladder and the abscess in the pelvis. This has occurred in patients with chronic osteomyelitis.

CLINICAL DIAGNOSES

Osteomyelitis, fifth lumbar vertebra (*Staph. aureus*).

Toxic hepatitis.

DR. NYE'S DIAGNOSES

Tuberculosis of spine, with abscess formation, secondary infection and dissection.

*Kimmelstiel, P. Symptom of jaundice occurring in newborn differential diagnosis. *Bull. Charlevoix Mem. Hosp.* 15:20, 1944

Pyelonephritis (probably secondary to amyloid disease of the kidneys).

Amyloid disease of liver?

ANATOMICAL DIAGNOSES

Tuberculosis of lumbar vertebrae, with paravertebral, psoas, groin and perinephric abscesses.

Tuberculosis of spleen, liver, left adrenal gland and bronchial lymph nodes.

Acute hepatitis, severe.

Jaundice.

Cystitis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy showed that the fourth and fifth lumbar vertebrae were involved in a necrotic process. There was a large

the spleen and liver contained several tubercles. The jaundice, however, was due not to a diffuse tuberculosis of the liver, but to a very acute necrotizing hepatitis, with widespread central destruction of the liver cells involving about two thirds of the parenchyma (Fig. 1). The liver cells were completely wiped out in many places, and there was a marked polymorphonuclear infiltration. The liver cells that were still recognizable as such were swollen and granular. There was no evidence of amyloid disease anywhere.

With the amount of liver destruction that this patient had it is difficult to explain the absence of clinical signs of liver damage until two days before death. Undoubtedly the liver damage was the immediate cause of death, and I believe that it

FIGURE 1.

abscess that involved the psoas muscles and communicated with a large perinephric abscess on the left side, which was filled with purulent material. He also had, of course, the draining sinuses and the abscess in the groin.

DR. COLBY: Did he have cortical abscesses of the kidneys?

DR. CASTLEMAN: No; the kidneys themselves were free from infection.

The bladder was injected and slightly trabeculated. The prostate was slightly enlarged. The liver was normal in size, slightly greenish and moderately soft. The adrenal glands were caseous, which at the time of autopsy gave a clue to the correct diagnosis. The microscopic sections showed tuberculosis of the vertebrae and of the adrenal glands, and

was directly related to the secondary infection.

Dr. Nye, how common is it to find a secondary invader so fulminating as this associated with tuberculosis?

DR. NYE: The patient never had a bacteremia during life. What were the findings at autopsy?

DR. CASTLEMAN: We were unable to recover a staphylococcus from the blood stream.

DR. NYE: I do not know how to explain the liver lesions. It is true that most chronic tuberculous infections that drain become secondarily infected. I should say that the severity of the secondary infection is dependent on the type of organism. Streptococcal infections are sometimes followed by extensive and even fatal hepatitis of the acute-yellow-atrophy type. A coagulase-positive *Staphylococcus*

aureus is a reasonably virulent organism under most circumstances, and that may have been the explanation.

CASE 30272

PRESENTATION OF CASE

A thirty-eight-year-old housewife was admitted to the hospital in coma.

The history was quite unsatisfactory and incomplete. She was first seen by her physician about three weeks before admission, at which time she gave a history of rheumatic fever in youth, with the recent development of increasing dyspnea, orthopnea and ankle edema but without fever or chest pain. Examination showed an enlarged liver, extending two or three fingerbreadths below the costal margin. Both lung bases were filled with rales. The heart was fibrillating, and apical systolic and diastolic murmurs were heard. She was placed on a salt-free diet, with limited fluid intake, 0.1 gm. ($1\frac{1}{2}$ gr.) of digitalis and 3 gm. of ammonium chloride daily and Mercupurin every three days. The pulse fell from 110 to 75, without change in the blood pressure, which was about 145 systolic, 90 diastolic. On this regime she improved rapidly, the ankle edema disappeared and she resumed her daily activities.

Two days before entry, while standing, she suddenly began to talk strangely, cried and felt depressed. Then without any convulsion or other complaint she fell to the floor in coma. She became aphasic, incontinent of urine and feces and unable to take anything by mouth. She could apparently move only the left side of the body.

Physical examination showed a well-developed, well-nourished comatose woman, with dry skin covered by many psoriatic lesions. The left pupil was smaller than the right. The pupils reacted to light, but the eyes wandered aimlessly. The fundi were normal. The lungs were clear. The left border of cardiac dullness was 13 cm. to the left of the midline in the fifth space. The sounds were distant. The heart was fibrillating. There was an apical systolic murmur. The aortic second sound was weaker than the pulmonic. The abdomen was negative except for the liver, which extended two fingerbreadths below the costal margin. The right arm and leg were paralyzed, with slightly hyperactive reflexes and bilateral positive Babinski signs. The neck was slightly stiff.

The blood pressure was 250 systolic, 120 diastolic. The temperature was 102.5°F., the pulse 100, and the respirations 25.

Examination of the blood showed a white-cell count of 12,800. The urine gave a specific gravity of 1.020 and a +++ test for albumin. The blood nonprotein nitrogen was 84 mg. per 100 cc., and the protein 7.2 gm. Blood Hinton and Wassermann

tests were negative. A lumbar puncture showed little if any increase in pressure. The fluid was clear and contained 80 lymphocytes and 20 polymorphonuclears per cubic millimeter; the total protein was 51 mg. per 100 cc., and the gold-sol curve 0023321000.

A stomach tube was passed, through which she was fed. She was given 0.1 gm. ($1\frac{1}{2}$ gr.) of digitalis and 1 gm. of ammonium chloride daily. She was quite restless and required restraint and paraldehyde almost every day.

On the second hospital day she developed Cheyne-Stokes respirations. The temperature, which had been steadily rising, went to 106°F. Coarse rales were heard in both bases, with many squeaking rales in the upper lung fields. She died on the third hospital day.

DIFFERENTIAL DIAGNOSIS

DR. AUGUSTUS S. ROSE: This case raises the perennial differential diagnostic problem — cerebral hemorrhage, thrombosis or embolism. When the record is first read the diagnosis seems clear; a second reading, however, makes another diagnosis seem just as evident; and a third reading, I confess, dispels one's conviction of either diagnosis.

The difficulties of clinical differentiation of apoplexy are notorious. Last evening I read the description in four modern textbooks of neurology and one of general medicine and found agreement only in that the diagnosis is difficult. Current literature offers little help. An article by Aring and Merritt* on the clinical differentiation between cerebral thrombosis and cerebral hemorrhage is excellent, but gives little aid in the immediate problem because of the strong implication of embolism.

This thirty-eight-year-old woman was apparently well until she developed clear-cut evidence of congestive heart failure in association with rheumatic heart disease. Appropriate medical therapy brought prompt improvement, but on return to activity she suddenly talked queerly, indicating involvement of the speech mechanism, and immediately fell to the floor in coma, with a right hemiplegia. When examined at the hospital two days later she was found to have a restless coma, a right hemiplegia, bilateral positive Babinski signs and unequal pupils.

The heart was fibrillating, and there were signs of congestive failure.

The spinal fluid was clear and colorless, containing 100 white cells per cubic millimeter but no red cells. The spinal-fluid pressure was within normal limits.

This spinal-fluid picture is certainly a surprise, and difficult, if not impossible, for me to fit with

*Aring, C. D., and Merritt, H. H. Differential diagnosis between cerebral hemorrhage and cerebral thrombosis: clinical and pathological study of 245 cases. *Arch. Int. Med.* 56:435-456, 1935.

the clinical picture. With cerebral hemorrhage, increased pressure and red cells are to be expected. With embolism and thrombosis, normal pressure and slightly yellow fluid with both white and red cells are usual.

The characteristic clinical picture of cerebral thrombosis differs considerably from what we have in this case. It is found in middle-aged or elderly patients with evidence of long-standing vascular disease. Signs develop slowly or at rest. Deep coma occurs if a sufficiently large vessel is involved, but most frequently it is a quiet, not a restless, coma. Pupillary difference is not usual, and many patients recover from the first episode, or at least live for many days.

Exclusion of hemorrhage or embolism is more difficult.

If for the moment we disregard the cardiac history and physical findings, we have a clinical picture that fits reasonably well with that seen in massive intracerebral hemorrhage, with the exception of the spinal fluid. Restlessness, coma, stiff neck, unequal pupils and bilateral Babinski signs can be evidence of midbrain compression, which is not infrequent in intracerebral bleeding. There is, however, no suggestion of pre-existing hypertension, and we cannot ignore the cardiac situation.

This patient had the ideal set-up for the development of a cerebral embolus. She had rheumatic heart disease, with auricular fibrillation and probable mitral stenosis. Having had a period of congestive failure and the accompanying cardiac dilatation, she had, on returning to activity, the rapid but not instantaneous onset of coma. By all logic, therefore, she must have had embolism. The neurologic manifestations should, however, be considered more closely.

The first symptom of queer, confused talk clearly points to interruption of the blood supply to the dominant hemisphere, but the rapidly ensuing coma suggests more widespread involvement than the branches of the left middle cerebral artery. Possibly the entire middle cerebral artery was occluded. But death followed more quickly than one would expect from occlusion of this artery alone. Furthermore, the signs suggesting midbrain compression do not fit. It is therefore necessary to suppose multiple lesions or to find the single lesion that would explain the brain-stem signs as well as the first symptom of confused speech. Occlusion of the vessels of the medulla would not produce this total picture, and although occlusion of the basilar artery could produce the neurologic signs, I do not believe that its occlusion would give the onset as seen in this case.

I am therefore left with the probable diagnosis of multiple cerebral embolism. The spinal-fluid cell count of 100 white cells, with 20 per cent polymorphonuclears, taken alone points to an infectious process, but we have no other evidence of infection.

DR. WYMAN RICHARDSON: How do you explain the renal findings?

DR. ROSE: I thought that they were of no particular importance regarding the cerebral affair or as a contributing cause of her death. The specific gravity of 1.020 suggests a reasonably good function, although if the dry skin, the albumin and the elevated blood nonprotein nitrogen are considered to be evidence of dehydration, the specific gravity should have been higher. I cannot see how these findings would have contributed to the cerebral episode unless they are evidence of a pre-existing vascular nephritis and a hypertension.

DR. RICHARDSON: You could, if you wanted to go rather far afield, say that she had a silent bacterial endocarditis associated with embolic nephritis. Of course that association is not infrequent. If one assumes that she had small emboli in the meninges from bacterial endocarditis, what sort of spinal fluid would have been found?

DR. ROSE: It would have been slightly hazy with not only white cells but also red cells, and probably some xanthochromia. In cerebral hemorrhage, too, one would expect xanthochromia, or even with thrombosis when the fluid is obtained as early in the course of the illness as this. I should call the absence of red cells in the spinal fluid the best indication that there were no infected emboli. In other words, the fluid was more inconsistent with emboli from bacterial endocarditis than with cerebral hemorrhage or embolism.

DR. JAMES B. AYER: Dr. Rose has referred to Aring and Merritt's paper; I should like to ask him what they say about the fluid in cases with a septic embolus.

DR. ROSE: Red cells are almost always present.

DR. AYER: Two years ago I saw a case of bacterial endocarditis in which emboli were being thrown off from time to time; the spinal fluid was slightly cloudy but contained no red cells. I believe that I have seen one other case without enough red cells to color the fluid.

DR. BENJAMIN CASTLEMAN: Does it not depend, Dr. Ayer, on the fact that if the emboli go to the meninges there results what may be called a bacterial meningitis, with red cells in the spinal fluid, whereas if they go to the large vessels within the brain, they produce infarction that does not necessarily come to the surface or reach the ventricular system?

DR. AYER: Or on whether there is subsequent hemorrhage into the area.

CLINICAL DIAGNOSES

Cerebrovascular accident.
Hypertensive, rheumatic heart disease.
Auricular fibrillation.
Psoriasis.

DR. ROSE'S DIAGNOSES

Rheumatic heart disease, with mitral stenosis.
Cerebral embolism, multiple.

ANATOMICAL DIAGNOSES

Rheumatic heart disease, with mitral, aortic and tricuspid stenosis.
Subacute bacterial endocarditis: mitral valve and left auricle.
Cerebral embolus: left internal carotid and middle cerebral arteries.
Cerebral infarction.
Embolic nephritis.
Pulmonary infarcts.
Thrombosis: posterior tibial vein.
Myocardial infarcts, miliary.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy, Dr. Charles S. Kubik found an embolus involving the terminal portion of the left internal carotid and the proximal portion of the middle cerebral artery that had produced infarction of the entire area supplied by the left middle cerebral artery and also a large part of the frontal lobe anteriorly, which is supplied by the anterior cerebral artery. The softening included the lenticular nucleus, the caudate nucleus and the internal capsule; in several small regions the soft tissues were hemorrhagic. Although he could not rule out

a localized thrombosis, he leaned a bit more toward embolism.

The autopsy also showed an enlarged heart, weighing over 600 gm., with rheumatic stenosis of the mitral, aortic and tricuspid valves, and a superimposed bacterial endocarditis of the mitral valve. There was an extensive bacterial endocarditis of the left auricle above the mitral valve, with the formation of mural thrombi, one of which, I believe, migrated to the internal carotid artery and produced the infarction.

The renal disease was embolic nephritis from the subacute bacterial endocarditis.

DR. ROSE: There were no red cells in the urine?

DR. CASTLEMAN: None are recorded.

This patient also had something unsuspected. There were numerous pulmonary infarcts that had been produced by emboli from thrombi in one of the posterior tibial veins. There was no jaundice.

DR. RICHARDSON: I believe that this is a characteristic feature in so-called "embolic nephritis" — a reasonably normal specific gravity and large amounts of albumin, although I should expect that there would also have been red cells. The last frequently appear in showers and might be missed in one examination.

DR. CASTLEMAN: There were small emboli to the heart itself, with miliary infarcts in the myocardium.

the usual course of the business of his employer and excepting domestic servants and farm laborers, shall be entitled to the voluntary benefits provided herein.

SECTION 2 *Present systems not affected.* Nothing herein shall be construed to affect any system in operation at the effective date of this act provided the benefits under such system equal the benefits provided herein and further provided that such system is approved by the Industrial Accident Board for the security of employees and any contract of insurance which is a part of such system shall be approved by the Insurance Commissioner as to the adequacy and reasonableness of premium charges and also as to form. Any person aggrieved by a ruling of the Industrial Accident Board or the Insurance Commissioner under this section may have a right of appeal to the Superior Court for a review thereof.

SECTION 3 *Election.* Any employee may elect to remain outside the provisions of this act provided he shall so notify his employer in writing within thirty days after the effective date of this act or if an employee is hired after the effective date of this act, then such notice shall be within ten days after his contract of hire. Any employee who has notified his employer of his election to remain outside the provisions of this act shall not be required to make any contribution by pay-roll deductions under this act.

SECTION 4 *Benefits.* Every employee who is unable to perform any services for wages because of his physical or mental condition, and has not given his employer notice in writing to remain outside this act, shall be entitled to the following specific benefits:

(a) *Cash sickness and bodily injury benefits.* Two thirds of the employee's average weekly wage but not to exceed \$20 per week. Payments to begin after two weeks' total disability because of physical or mental condition provided that a certificate from a duly licensed physician is procured to support the disability. The payments for one continuing disability shall be limited to twenty-six weeks.

(b) *Hospital benefits.* An employee shall be allowed for confinement in a legally chartered hospital expenses up to \$4 per day, not exceeding sixty days during each period of disability. The employee shall also be allowed up to \$20 for operating room, x-ray, laboratory and anesthetic fees. The employee shall have the right to choose a hospital of his own choice.

(c) *Surgical operation benefits.* An employee shall be allowed for surgical operation benefits up to \$100 for an operation performed by a duly licensed physician. A schedule of fees for operations shall be determined by the Industrial Accident Board. The employee shall have the right to choose a physician of his own choice, provided that such physician is duly licensed in this commonwealth.

(d) *Maternity benefits.* Any female employee shall be entitled to cash sickness benefits for a period of six weeks of disability because of pregnancy provided such employee has been under this act for a period of not less than ten months. Hospital benefits for such female employee shall not exceed a rate of \$4 per day for a period up to ten days and such employee shall be allowed for delivery expenses the sum of \$50. Such employee may choose a physician of her own choice provided such physician is duly licensed in this commonwealth.

SECTION 5 *Coverage.* In order to promote the health, safety and welfare of employees, every employer under this act shall provide a voluntary system for the payment of benefits to his employees who are under this act in the following manner:

(a) *Insurance.* By procuring an insurance policy from an insurance company authorized to do business in this commonwealth in such form as may be required by the Insurance Commissioner. The employer shall be entitled to reimbursement for one half the cost of such insurance from his employees by payroll deductions. Such policy shall not be effective until the premium charges shall be approved by the Insurance Commissioner as adequate, fair and reasonable; or

(b) *Self-insurance.* By furnishing the Industrial Accident Board satisfactory proof of his financial ability to pay the benefits prescribed by this act to his employees by furnishing securities, bond or indemnity in an amount satis-

factory to the Industrial Accident Board; such employee shall be entitled to reimbursement from his employer for one half the cost of the coverage by payroll deduction. The premium charges for such indemnity or bond or any other form of insurance contract shall be approved by the Insurance Department as adequate, fair and reasonable. The forms for such indemnity, bond or other insurance contract shall be approved by the Insurance Commissioner.

(c) *Rules.* The Industrial Accident Board may make rules consistent with this act for the proper carrying out of its provisions.

SECTION 6. *Termination.* An employee's right to benefits under the provisions of this act terminates on the date he severs his employment unless on that date he is suffering a disability which entitles him to the benefits provided herein. An employee may terminate his rights to the benefits under this act by giving to his employer a notice in writing effective upon the expiration of thirty days.

SECTION 7. *Hearings and appeals.* Any employee, self-insured employer or insurance company may request the Industrial Accident Board for a hearing at any time on the issue of whether an employee is entitled to the benefits of the provisions of this act. Any person aggrieved by the decision of the Industrial Accident Board may have a right of appeal to the Superior Court.

SECTION 8. *Physical examination.* The insurance company, self-insured employer or Industrial Accident Board shall be entitled to a physical examination of an employee receiving benefits under this act provided that such examining physician is duly licensed to practice in this commonwealth.

SECTION 9. *Assignment of rejected risks.* An employer who has been refused insurance under this act may appeal to the Insurance Commissioner, who shall make an equitable distribution of such refused risks among insurance companies authorized to write insurance under this act.

SECTION 10. *Benefits outside this act.* Any person who is entitled to workmen's compensation benefit, or unemployment compensation, shall not be entitled to the voluntary benefits of this act.

SECTION 11. *Effective date.* This act shall take effect on January 1, 1945.

DEATHS

VARNEY — Fred E. Varney, M.D., of North Chelmsford, died June 7. He was in his eighty-fourth year.

Dr. Varney received his degree from Bowdoin Medical School, in 1886. At the time of his retirement in 1936, the Massachusetts Medical Society honored him with the presentation of a medal commemorating fifty years' service to humanity.

His widow, a son, and a brother survive.

WATSON — Lester D. Watson, M.D., formerly of Milton, died June 14. He was in his forty-fourth year.

Dr. Watson received his degree from Boston University School of Medicine in 1928. He was formerly on the staff of the Milton Hospital and associated with the Massachusetts Memorial Hospitals. Recently he had been stationed on Long Island, New York, as assistant surgeon of the U.S. Public Health Service. He was a member of the American Medical Association and a fellow of the American College of Physicians.

His widow, two sons and a sister survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

EMERGENCY MATERNITY AND INFANT CARE PROGRAM

CONSULTANT SERVICE

A new standard for consultant service has been established in Massachusetts for the Emergency Maternity and Infant Care Program. A consultant paid under this program may be a diplomate in any

the usual course of the business of his employer and excepting domestic servants and farm laborers, shall be entitled to the voluntary benefits provided herein.

SECTION 2. *Present systems not affected.* Nothing herein shall be construed to affect any system in operation at the effective date of this act provided the benefits under such system equal the benefits provided herein and further provided that such system is approved by the Industrial Accident Board for the security of employees and any contract of insurance which is a part of such system shall be approved by the Insurance Commissioner as to the adequacy and reasonableness of premium charges and also as to form. Any person aggrieved by a ruling of the Industrial Accident Board or the Insurance Commissioner under this section may have a right of appeal to the Superior Court for a review thereof.

SECTION 3. *Election.* Any employee may elect to remain outside the provisions of this act provided he shall so notify his employer in writing within thirty days after the effective date of this act or if an employee is hired after the effective date of this act, then such notice shall be within ten days after his contract of hire. Any employee who has notified his employer of his election to remain outside the provisions of this act shall not be required to make any contribution by pay-roll deductions under this act.

SECTION 4. *Benefits.* Every employee who is unable to perform any services for wages because of his physical or mental condition, and has not given his employer notice in writing to remain outside this act, shall be entitled to the following specific benefits:

(a) *Cash sickness and bodily injury benefits.* Two thirds of the employee's average weekly wage but not to exceed \$20 per week. Payments to begin after two weeks' total disability because of physical or mental condition provided that a certificate from a duly licensed physician is procured to support the disability. The payments for one continuing disability shall be limited to twenty-six weeks.

(b) *Hospital benefits.* An employee shall be allowed for confinement in a legally chartered hospital expenses up to \$4 per day, not exceeding sixty days during each period of disability. The employee shall also be allowed up to \$20 for operating room, x-ray, laboratory and anesthetic fees. The employee shall have the right to choose a hospital of his own choice.

(c) *Surgical operation benefits.* An employee shall be allowed for surgical operation benefits up to \$100 for an operation performed by a duly licensed physician. A schedule of fees for operations shall be determined by the Industrial Accident Board. The employee shall have the right to choose a physician of his own choice, provided that such physician is duly licensed in this commonwealth.

(d) *Maternity benefits.* Any female employee shall be entitled to cash sickness benefits for a period of six weeks of disability because of pregnancy provided such employee has been under this act for a period of not less than ten months. Hospital benefits for such female employee shall not exceed a rate of \$4 per day for a period up to ten days and such employee shall be allowed for delivery expenses the sum of \$50. Such employee may choose a physician of her own choice provided such physician is duly licensed in this commonwealth.

SECTION 5. *Coverage.* In order to promote the health, safety and welfare of employees, every employer under this act shall provide a voluntary system for the payment of benefits to his employees who are under this act in the following manner:

(a) *Insurance.* By procuring an insurance policy from an insurance company authorized to do business in this commonwealth in such form as may be required by the Insurance Commissioner. The employer shall be entitled to reimbursement for one half the cost of such insurance from his employees by payroll deductions. Such policy shall not be effective until the premium charges shall be approved by the Insurance Commissioner as adequate, fair and reasonable; or

(b) *Self-insurance.* By furnishing the Industrial Accident Board satisfactory proof of his financial ability to pay the benefits prescribed by this act to his employees by furnishing securities, bond or indemnity in an amount satis-

factory to the Industrial Accident Board; such employer shall be entitled to reimbursement from his employees for one half the cost of the coverage by payroll deductions. The premium charges for such indemnity or bond or any other form of insurance contract shall be approved by the Insurance Department as adequate, fair and reasonable. The forms for such indemnity, bond or other insurance contract shall be approved by the Insurance Commissioner.

(c) *Rules.* The Industrial Accident Board may make rules consistent with this act for the proper carrying out of its provisions.

SECTION 6. *Termination.* An employee's right to benefits under the provisions of this act terminates on the date he severs his employment unless on that date he is suffering a disability which entitles him to the benefits provided herein. An employee may terminate his rights to the benefits under this act by giving to his employer a notice in writing effective upon the expiration of thirty days.

SECTION 7. *Hearings and appeals.* Any employee, self-insured employer or insurance company may request the Industrial Accident Board for a hearing at any time on the issue of whether an employee is entitled to the benefits of the provisions of this act. Any person aggrieved by the decision of the Industrial Accident Board may have a right of appeal to the Superior Court.

SECTION 8. *Physical examination.* The insurance company, self-insured employer or Industrial Accident Board shall be entitled to a physical examination of an employee receiving benefits under this act provided that such examining physician is duly licensed to practice in this commonwealth.

SECTION 9. *Assignment of rejected risks.* An employer who has been refused insurance under this act may appeal to the Insurance Commissioner, who shall make an equitable distribution of such refused risks among insurance companies authorized to write insurance under this act.

SECTION 10. *Benefits outside this act.* Any person who is entitled to workmen's compensation benefit, or unemployment compensation, shall not be entitled to the voluntary benefits of this act.

SECTION 11. *Effective date.* This act shall take effect on January 1, 1945.

Payments to begin after two weeks' total disability because of physical or mental condition provided that a certificate from a duly licensed physician is procured to support the disability. The payments for one continuing disability shall be limited to twenty-six weeks.

(b) *Hospital benefits.* An employee shall be allowed for confinement in a legally chartered hospital expenses up to \$4 per day, not exceeding sixty days during each period of disability. The employee shall also be allowed up to \$20 for operating room, x-ray, laboratory and anesthetic fees. The employee shall have the right to choose a hospital of his own choice.

(c) *Surgical operation benefits.* An employee shall be allowed for surgical operation benefits up to \$100 for an operation performed by a duly licensed physician. A schedule of fees for operations shall be determined by the Industrial Accident Board. The employee shall have the right to choose a physician of his own choice, provided that such physician is duly licensed in this commonwealth.

(d) *Maternity benefits.* Any female employee shall be entitled to cash sickness benefits for a period of six weeks of disability because of pregnancy provided such employee has been under this act for a period of not less than ten months. Hospital benefits for such female employee shall not exceed a rate of \$4 per day for a period up to ten days and such employee shall be allowed for delivery expenses the sum of \$50. Such employee may choose a physician of her own choice provided such physician is duly licensed in this commonwealth.

SECTION 5. *Coverage.* In order to promote the health, safety and welfare of employees, every employer under this act shall provide a voluntary system for the payment of benefits to his employees who are under this act in the following manner:

(a) *Insurance.* By procuring an insurance policy from an insurance company authorized to do business in this commonwealth in such form as may be required by the Insurance Commissioner. The employer shall be entitled to reimbursement for one half the cost of such insurance from his employees by payroll deductions. Such policy shall not be effective until the premium charges shall be approved by the Insurance Commissioner as adequate, fair and reasonable; or

(b) *Self-insurance.* By furnishing the Industrial Accident Board satisfactory proof of his financial ability to pay the benefits prescribed by this act to his employees by furnishing securities, bond or indemnity in an amount satis-

factory to the Industrial Accident Board; such employee shall be entitled to reimbursement from his employer for one half the cost of the coverage by payroll deduction. The premium charges for such indemnity or bond or any other form of insurance contract shall be approved by the Insurance Department as adequate, fair and reasonable. The forms for such indemnity, bond or other insurance contract shall be approved by the Insurance Commissioner.

(c) *Rules.* The Industrial Accident Board may make rules consistent with this act for the proper carrying out of its provisions.

SECTION 6. *Termination.* An employee's right to benefits under the provisions of this act terminates on the date he severs his employment unless on that date he is suffering a disability which entitles him to the benefits provided herein. An employee may terminate his rights to the benefits under this act by giving to his employer a notice in writing effective upon the expiration of thirty days.

SECTION 7. *Hearings and appeals.* Any employee, self-insured employer or insurance company may request the Industrial Accident Board for a hearing at any time on the issue of whether an employee is entitled to the benefits of the provisions of this act. Any person aggrieved by the decision of the Industrial Accident Board may have a right of appeal to the Superior Court.

SECTION 8. *Physical examination.* The insurance company, self-insured employer or Industrial Accident Board shall be entitled to a physical examination of an employee receiving benefits under this act provided that such examining physician is duly licensed to practice in this commonwealth.

SECTION 9. *Assignment of rejected risks.* An employer who has been refused insurance under this act may appeal to the Insurance Commissioner, who shall make an equitable distribution of such refused risks among insurance companies authorized to write insurance under this act.

SECTION 10. *Benefits outside this act.* Any person who is entitled to workmen's compensation benefit, or unemployment compensation, shall not be entitled to the voluntary benefits of this act.

SECTION 11. *Effective date.* This act shall take effect on January 1, 1945.

DEATHS

VARNEY — Fred E. Varney, M.D., of North Chelmsford, died June 7. He was in his eighty-fourth year.

Dr. Varney received his degree from Bowdoin Medical School, in 1886. At the time of his retirement in 1936, the Massachusetts Medical Society honored him with the presentation of a medal commemorating fifty years' service to humanity.

His widow, a son, and a brother survive.

WATSON — Lester D. Watson, M.D., formerly of Milton, died June 14. He was in his forty-fourth year.

Dr. Watson received his degree from Boston University School of Medicine in 1928. He was formerly on the staff of the Milton Hospital and associated with the Massachusetts Memorial Hospitals. Recently he had been stationed on Long Island, New York, as assistant surgeon of the U. S. Public Health Service. He was a member of the American Medical Association and a fellow of the American College of Physicians.

His widow, two sons and a sister survive.

EMERGENCY MATERNITY AND INFANT CARE PROGRAM

CONSULTANT SERVICE

A new standard for consultant service has been established in Massachusetts for the Emergency Maternity and Infant Care Program. A consultant paid under this program may be a diplomate in any

the usual course of the business of his employer and excepting domestic servants and farm laborers, shall be entitled to the voluntary benefits provided herein.

Section 2. *Present systems not affected.* Nothing herein shall be construed to affect any system in operation at the effective date of this act provided the benefits under such system equal the benefits provided herein and further provided that such system is approved by the Industrial Accident Board for the security of employees and any contract of insurance which is a part of such system shall be approved by the Insurance Commissioner as to the adequacy and reasonableness of premium charges and also as to form. Any person aggrieved by a ruling of the Industrial Accident Board or the Insurance Commissioner under this section may have a right of appeal to the Superior Court for a review thereof.

Section 3. *Election.* Any employee may elect to remain outside the provisions of this act provided he shall so notify his employer in writing within thirty days after the effective date of this act or if an employee is hired after the effective date of this act, then such notice shall be within ten days after his contract of hire. Any employee who has notified his employer of his election to remain outside the provisions of this act shall not be required to make any contribution by pay-roll deductions under this act.

Section 4. *Benefits.* Every employee who is unable to perform any services for wages because of his physical or mental condition, and has not given his employer notice in writing to remain outside this act, shall be entitled to the following specific benefits:

(a) *Cash sickness and bodily injury benefits.* Two thirds of the employee's average weekly wage but not to exceed \$20 per week. Payments to begin after two weeks' total disability because of physical or mental condition provided that a certificate from a duly licensed physician is procured to support the disability. The payments for one continuing disability shall be limited to twenty-six weeks.

(b) *Hospital benefits.* An employee shall be allowed for confinement in a legally chartered hospital expenses up to \$4 per day, not exceeding sixty days during each period of disability. The employee shall also be allowed up to \$20 for operating room, x-ray, laboratory and anesthetic fees. The employee shall have the right to choose a hospital of his own choice.

(c) *Surgical operation benefits.* An employee shall be allowed for surgical operation benefits up to \$100 for an operation performed by a duly licensed physician. A schedule of fees for operations shall be determined by the Industrial Accident Board. The employee shall have the right to choose a physician of his own choice, provided that such physician is duly licensed in this commonwealth.

(d) *Maternity benefits.* Any female employee shall be entitled to cash sickness benefits for a period of six weeks of disability because of pregnancy provided such employee has been under this act for a period of not less than ten months. Hospital benefits for such female employee shall not exceed a rate of \$4 per day for a period up to ten days and such employee shall be allowed for delivery expenses the sum of \$50. Such employee may choose a physician of her own choice provided such physician is duly licensed in this commonwealth.

(e) *Funeral benefits.* In order to promote the health, safety and welfare of employees, every employer under this act shall provide a voluntary system for the payment of benefits to his employees who are under this act in the following manner:

(a) *Insurance.* By procuring an insurance policy from an insurance company authorized to do business in this commonwealth in such form as may be required by the Insurance Commissioner. The employer shall be entitled to reimbursement for one half the cost of such insurance from his employees by payroll deductions. Such policy shall not be effective until the premium charges shall be approved by the Insurance Commissioner as adequate, fair and reasonable; or

(b) *Self-insurance.* By furnishing the Industrial Accident Board satisfactory proof of his financial ability to pay the benefits prescribed by this act to his employees by furnishing securities, bond or indemnity in an amount satisfactory to the Board.

then only if ice refrigerating equipment cannot be used. The War Production Board has approved the production of ice refrigerators, which may be sold through retail outlets without restriction.

The companies manufacturing electric refrigerators in the United States have been completely converted to war production. The present policy of the War Production Board, with respect to the reconversion of an industry that has contributed so vastly to the war production program, such as the refrigeration industry, is that until the impending military operations become clarified no consideration can be given to the matter of resumption of production.

Owing to the fact that there are certain types of industrial institutions, research testing laboratories, dietetic laboratories and professional men who definitely require mechanical refrigerators, as well as Army, Navy, Maritime and other military demands, the remaining supply must be carefully guarded.

The War Production Board in Washington has requested the field offices to thoroughly investigate every possible way of satisfying the applicants' needs without the use of an electric refrigerator. We in the War Production Board request the co-operation of the professional men in assisting us to obtain fair distribution of the limited quantity we have left. Applications should not be filed by anyone unless the required results cannot be obtained through the use of ice.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Symptoms and Signs in Clinical Medicine: An introduction to medical diagnosis. By E. Noble Chamberlain, M.D., M.Sc., F.R.C.P., lecturer in medicine, University of Liverpool, physician to outpatients, Royal Liverpool United Hospital, Royal Infirmary Branch, and visiting physician, Smithdown Road Hospital, Liverpool. Third edition. 8°, cloth, 456 pp., with 346 illustrations. Baltimore: The Williams and Wilkins Company, 1943. \$8.00.

This book was printed in Great Britain but bound and distributed in the United States under an American imprint. It has been popular, since the first edition was issued in April, 1936. The work has been considerably revised to bring it up to date. Additions have been made to the chapters on endocrine defects, on the symptoms and signs of respiratory diseases and on the cardiovascular system. The classification of anemias has been altered to bring it more into line with modern pathological concepts. The manual is well printed on good paper and strongly bound.

A Medical Bibliography: A check-list of texts illustrating the history of the medical sciences. Originally compiled by the late Fielding H. Garrison, M.D., and now revised, with additions and annotations, by Leslie T. Morton, librarian, St. Thomas's Hospital Medical School. 8°, cloth, 412 pp. London: Grafton and Company, 1943. £2.10s.

This is an amplification of notes of the original work of Dr. Fielding H. Garrison, published by him in the *Index Catalogue* of the Surgeon General's Office in 1912. Dr. Garrison's original list did not have any comments on the various titles that he included in his list of classics. This has been largely added to by Mr. Morton, with a comment on each title.

Holt's Care and Feeding of Children. Revised and enlarged by L. Emmett Holt, Jr., M.D., associate professor of pediatrics, Johns Hopkins University, and associate pediatrician, Johns Hopkins Hospital, Baltimore. 12°, cloth, 321 pp. New York: D. Appleton-Century Company, Incorporated, 1943. \$2.00.

This popular manual, first published in 1894, has passed through many editions under the authorship of the Holts, father and son. The work is divided into two classes of children: infants and older children. In addition to the chapters on breast feeding and artificial feeding, there is one on growth and nutrition of older children, one on behavior problems and one on the common ailments of childhood.

The Foot. By Norman C. Lake, M.D., M.S., D.Sc. (Lond.), F.R.C.S. (Eng.), senior surgeon and lecturer on surgery, Charing Cross Hospital, surgeon, Bolingbroke Hospital, consulting surgeon, Emergency Medical Service, and director of studies, London Foot Hospital. Third edition. 8°, cloth, 432 pp., with 136 illustrations. Baltimore: The Williams and Wilkins Company, 1943. \$5.00.

This third edition of a standard work has been revised to include new material on gunshot wounds, trench foot, immersion foot and foot fatigue, as observed in industry and the armed services. Other new material has been included, especially a section on gait and one on the etiology of various diseases. A number of new illustrations have been added, increasing the book somewhat in size. The work was printed in Great Britain but bound and distributed in the United States. It has long been looked on as an authoritative textbook on its subject.

Surgical Errors and Safeguards. By Max Thorek, M.D., LL.D., professor of surgery, Cook County Graduate School of Medicine, attending surgeon, Cook County Hospital, surgeon-in-chief, American Hospital, and consulting surgeon, Municipal Tuberculosis Sanitarium. With a foreword by Sir Hugh Devine, M.S., F.R.C.S. (hon.) (Eng.) F.R.A.C.S., F.A.C.S. (hon.), F.I.C.S. (hon.), and a chapter on legal responsibility in surgical practice by Hubert W. Smith, M.B.A., LL.B., M.D., associate in medicolegal research, Harvard Law School and Harvard Medical School, Boston. Fourth edition, completely revised. 8°, cloth, 1085 pp., with 794 illustrations. Philadelphia: J. B. Lippincott Company, 1943. \$15.00.

The first edition of this book was published in 1932, and the popularity of the work is evidenced by the necessity for successive editions in 1934, 1937 and 1943. The first edition was based primarily on the author's own observations and experiences, whereas this new edition is a compendium of experiences throughout the world. The work has been completely rewritten, and in keeping with the times, new chapters on errors and safeguards in plastic and electrosurgical operations and on the medicolegal aspects of surgical practice have been added. The work is copiously illustrated and printed with a good type on good paper.

The Harvey Cushing Collection of Books and Manuscripts. Publication No. 1. Historical Library, Yale Medical Library. 4°, cloth, 207 pp. New York: Schuman's, 1943. \$8.50.

Dr. Cushing was one of the great collectors in the field of medicine during the present era. His library is now housed in a special building in the Yale Medical School. This catalogue is an enumeration of the works contained in the library at the time of its transfer to Yale.

Holt's Care and Feeding of Children. Revised and enlarged by L. Emmett Holt, Jr., M.D., associate professor of pediatrics, Johns Hopkins University, and associate pediatrician, Johns Hopkins Hospital, Baltimore. 12, cloth, 321 pp. New York: D. Appleton-Century Company, Incorporated, 1943. \$2.00.

A Medical Bibliography: A check-list of texts illustrating the history of the medical sciences. Originally compiled by the late Fielding H. Garrison, M.D., and now revised, with additions and annotations, by Leslie T. Morton, M.D., St. Thomas's Hospital Medical School. 8, cloth, 412 pp. London: Grafton and Company, 1943. £2.10s.

This is an amplification of notes of the original work of Dr. Fielding H. Garrison, published by him in the Index Catalogue of the Surgeon General's Office in 1912. Dr. Garrison's original list did not have any comments on the various titles that he included in his list of classics. This has been largely added to by Mr. Morton, with a comment on each title.

The Foot. By Norman C. Lake, M.D., D.Sc. (Lond.), F.R.C.S. (Eng.), senior surgeon and lecturer on surgery, Charing Cross Hospital, surgeon, Brompton Hospital, consulting surgeon, Emergency Medical Service, and director of studies, London Foot Hospital. Third edition. 8, cloth, 432 pp., with 136 illustrations. Baltimore: The Williams and Wilkins Company, 1943. \$5.00.

This third edition of a standard work has been revised to include new material on gunshot wounds, trench foot, immersion foot and foot fatigue, as observed in industry and the armed services. Other new material has been included, especially a section on gait and one on the etiology of various diseases. A number of new illustrations have been added, increasing the book somewhat in size. The work was printed in Great Britain but bound and distributed in the United States. It has long been looked on as an authoritative textbook on its subject.

Surgical Errors and Safeguards. By Max Thorek, M.D., L.D., professor of surgery, Cook County Graduate School of Medicine, attending surgeon, Cook County Hospital, surgeon-in-chief, American Hospital, and consulting surgeon, Municipal Tuberculosis Sanitarium. With a foreword by Sir Hugh Deane, M.S., F.R.C.S. (Hon.) (Eng.), F.R.A.C.S., F.A.C.S. (Hon.), F.I.C.S. (Hon.), and a chapter on legal responsibility in surgical practice by Hubert W. Smith, M.B.A., LL.B., M.D., associate in medical research, Harvard Law School and Harvard Medical School, Boston. Fourth edition, completely revised. 8, cloth, 1085 pp., with 794 illustrations. Philadelphia: J. B. Lippincott Company, 1943. \$15.00.

The first edition of this book was published in 1932, and the popularity of the work is evidenced by the necessity for successive editions in 1934, 1937 and 1943. The first edition was based primarily on the author's own observations and experiences, whereas this new edition is a compendium of experiences throughout the world. The work has been completely rewritten, and in keeping with the times, new chapters on errors and safeguards in plastic and electrosurgical operations and on the medical aspects of surgical practice have been added. The work is copiously illustrated and printed with a good type on good paper.

The Harvey Cushing Collection of Books and Manuscripts. Publication No. 1. Historical Library, Yale Medical Library. New York: Schuman's, 1943. \$8.50. 4, cloth, 207 pp.

Dr. Cushing was one of the great collectors in the field of medicine during the present era. His library is now housed in a special building in the Yale Medical School. This catalogue is an enumeration of the works contained in the library at the time of its transfer to Yale. (Notices on page xiii)

This book was printed in Great Britain but bound and distributed in the United States under an American imprint. It has been popular, since the first edition was issued in April, 1936. The work has been considerably revised to bring it up to date. Additions have been made to the chapters on endocrine defects, on the symptoms and signs of respiratory diseases and on the cardiovascular system. The classification of anemias has been altered to bring it more into line with modern pathological concepts. The manual is well printed on good paper and strongly bound.

Symptoms and Signs in Clinical Medicine: An introduction to medical diagnosis. By E. Noble Chamberlain, M.D., M.Sc., F.R.C.P., lecturer in medicine, University of Liverpool, physician to outpatients, Royal Liverpool United Hospital, Royal Infirmary Branch, and visiting physician, Smithdown Road Hospital, Liverpool. Third edition. 8, cloth, 456 pp., with 346 illustrations. Baltimore: The Williams and Wilkins Company, 1943. \$8.00.

then only if ice refrigerating equipment cannot be used. The War Production Board has approved the production of ice refrigerators, which may be sold through retail outlets without restriction.

The companies manufacturing electric refrigerators in the United States have been completely converted to war production. The present policy of the War Production Board, with respect to the reconversion of an industry that has contributed so vastly to the war production program, such as the refrigeration industry, is that until the impending military operations become clarified no consideration can be given to the matter of resumption of production.

Owing to the fact that there are certain types of industrial institutions, research testing laboratories, dietetic laboratories and professional men who definitely require mechanical refrigerators, as well as Army, Navy, Maritime and other military demands, the remaining supply must be carefully guarded.

The War Production Board in Washington has requested the field offices to thoroughly investigate every possible way of satisfying the applicants' needs without the use of an electric refrigerator. We in the War Production Board request the co-operation of the professional men in assisting us to obtain fair distribution of the limited quantity we have left. Applications should not be filed by anyone unless the required results cannot be obtained through the use of ice.

HODGKIN'S DISEASE*

II. Pathology

HENRY JACKSON, JR., M.D.,† AND FREDERIC PARKER, JR., M.D.‡

BOSTON

IN THE present paper there will be discussed the gross and microscopic features of the three types of Hodgkin's disease, the apparent site of origin in each and the extent to which each form involves the various organs of the body. Without some knowledge of the gross pathology and the distribution of the lesions one cannot hope to have a clear understanding of the clinical capacities of the disease.

HODGKIN'S PARAGRANULOMA

Hodgkin's paraganuloma appears to be a disease essentially of the lymph nodes. Those involved are most frequently found in the neck and are usually few in number, discrete, of rubbery consistence and not attached to the surrounding tissue (Table 1).

TABLE 1. *Apparent Primary Site of Disease in Cases of Hodgkin's Paraganuloma.*

	No OF CASES

Axillary lymph nodes	1
Total	26

They are rarely more than 3 cm. in diameter and on cut section are yellowish gray. There is no evidence of softening or necrosis, and the capsule is intact.

On microscopic examination the normal structure of the lymph node as a whole is occasionally unaffected; more commonly it is partly or entirely lost. In some cases the lymph follicles are preserved and show only varying degrees and types of cellular activity; in others they are partly or completely obliterated. The peripheral sinus may be clearly outlined or be compressed by the follicles or obscured by actual cellular infiltration.

*From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard) and the Mallory Institute of Pathology, Boston City Hospital, and the Department of Medicine, Harvard Medical School.

†Assistant professor of medicine, Harvard Medical School, associate physician, Thorndike Memorial Laboratory, Boston City Hospital

‡Associate professor of pathology, Harvard Medical School, pathologist-in-chief, Boston City Hospital.

The diagnosis is based on the presence, within the involved nodes, of Reed-Sternberg cells, which may be few or numerous. They occur especially in the pulp; more rarely they are seen in the lymph follicles. These large cells with multilobed or more rarely multiple nuclei and prominent nucleoli are indistinguishable from those found in the other forms of Hodgkin's disease. The cytoplasm is fairly abundant and tends to be amphophilic. Mitotic figures in the Reed-Sternberg cells of this form of Hodgkin's disease are not numerous.

The predominant cell of Hodgkin's paraganuloma is, however, the adult lymphocyte. In cases in which the lymph follicles have been obliterated, the diffuse infiltration of the nodes by lymphocytes may be so great that an erroneous diagnosis of lymphocytoma is easily made. Buried within this mass of lymphocytes are found, nevertheless, the typical Reed-Sternberg cell, for which a careful search must be made not infrequently. Reticulum cells, often containing phagocytosed debris, are present in varying numbers. In some cases they occur as focal aggregates resembling the lesions of Boeck's sarcoid. Plasma cells are not uncommonly seen and may be numerous. Eosinophils are sometimes present, but never in such quantities as in Hodgkin's granuloma.

The pathologic process never invades the capsule, although there may be an infiltration of this structure by scattered lymphocytes and plasma cells. In Hodgkin's paraganuloma one never sees the necrosis, the infiltration with polymorphonuclear leukocytes, the marked eosinophilia or the fibrosis so frequently found in Hodgkin's granuloma.

The changes in the reticulum vary widely. In some cases it is normal in amount; in others there is an increase in the number of fibers in the medullary cords but not in the follicles. In still others the fibers are thickened, but this change is usually associated with scarring due to some independent and unrelated process.

It should be pointed out that in certain cases of Hodgkin's paraganuloma the presence of fairly numerous eosinophils and fibrin is evidence that

a transformation into the granulomatous form is impending, and transitional types of the disease occur in which it is difficult to be sure whether one is dealing with Hodgkin's paraganuloma or with Hodgkin's granuloma. It may be argued that those cases of Hodgkin's paraganuloma that fail to change into Hodgkin's granuloma represent, indeed, an entirely different disease. It must be remembered, however, that those that progress cannot, in their incipency, be distinguished from those that do not. For instance, in 1910 one of our patients had a cervical lymph node removed that showed the typical picture of Hodgkin's paraganuloma. Subsequent biopsies from the neck in 1917 and 1936 showed a histologic picture indistinguishable from that seen in 1910. The patient has continued to be in good health to date. On the other hand, a second patient in 1941 had a cervical lymph node removed that showed the typical histologic picture of Hodgkin's paraganuloma. He was given a moderate amount of high-voltage x-ray treatment and continued in apparently good health until 1943, at which time he suddenly became progressively worse, with all the signs and symptoms usually associated with advanced Hodgkin's granuloma. Autopsy showed extremely extensive involvement with the granulomatous type of the disease. The initial biopsy specimens from these two cases were indistinguishable. In the first case, the type of lesion did not alter over a period of twenty-six years, and the patient was alive and active thirty-eight years after the initial lymphadenopathy had been noted. In the second case, on the other hand, the histologic picture changed with considerable rapidity and death shortly ensued. A third patient had a large mass of nodes dissected from the neck in 1920. He remained active and in apparent good health until 1943, when he returned with a large mediastinal mass and a few lymph nodes in the neck. These proved on biopsy to be Hodgkin's granuloma. In 3 other cases, Hodgkin's granuloma developed as proved by autopsy. Four patients died of unrelated causes such as carcinoma or tuberculosis, and 5 died from causes unknown. Unfortunately, no autopsy was obtained in any of the latter cases. Thirteen patients are alive and active, although some still show evidence of their disease.

It should be emphasized that so long as the pathologic process remains unaltered the prognosis is relatively good, but in certain cases Hodgkin's granuloma develops, and the prognosis then becomes that of the latter condition.

If the pathologic process remains that of Hodgkin's paraganuloma, involvement of the internal organs appears to be rare. In 4 cases, the mediastinal nodes became involved. Three of these patients are still alive, and 1 died of pulmonary tuberculosis. In 2 cases, the spleen became definitely enlarged. Each of these patients died at home of

unknown causes. In 3 cases, both the mediastinal nodes and spleen became involved. All these patients have died. There were no autopsies.

HODGKIN'S GRANULOMA

The granulomatous process may involve isolated groups of nodes in certain regions, or the process may be widespread. In our series of cases, the lymph nodes were implicated to some extent in every case. Cases have been reported, however, in which the disease was confined to a single organ with no lymph-node involvement, such as the 2 cases mentioned by Sternberg¹ in which the spleen alone was diseased.

From autopsy studies of 59 cases, it is shown that the retroperitoneal and para-aortic lymph nodes were the most frequent primary site of the disease, followed by other lymph nodes and the stomach or intestines (Table 2). This is in sharp contrast to

TABLE 2. Primary Site of Disease in Cases of Hodgkin's Granuloma.

SITE	No. of Cases

the clinical observations, from which it appears that the cervical nodes were the primary site in an overwhelming percentage of the cases. It is probable that the favorable response of the more superficial nodes to x-ray therapy and the difficulty of recognizing during life involvement of the deeper nodes and internal organs account for this apparent discrepancy. But the fact that internal lymph nodes are so frequently involved at autopsy and primarily so, even though they have been suspected of being implicated during life, should make the physician cautious before deciding, in a given case, that the disease is confined to a small number of obviously involved but comparatively localized superficial nodes.

The diseased lymph nodes often occur in masses, but the outlines of each can usually be made out. Their consistence may be soft or firm, but with deposition of connective tissue the nodes become increasingly harder. Only rarely, however, do they assume the stony hardness so suggestive of carcinoma. The cut surface is grayish white, often with a brownish tint. It may be homogeneous or may show foci of necrosis, which are of varied shape and are white to yellow. In our experience, breaking down or softening due to Hodgkin's granuloma alone does not occur. Secondary in-

fection, particularly in the groin, may, however, give rise to abscess formation or the deposition of scar tissue to such an extent that a definitive diagnosis is impossible. If feasible, it is always wise to avoid the removal of a node from the groin and to choose for biopsy a lymph node in the neck or axilla, provided that there is one of sufficient size and that it is readily accessible.

The histologic picture of Hodgkin's granuloma is characterized by the presence of Reed-Sternberg cells and by its great pleomorphism. The lymph nodes involved as a rule show complete loss of their normal architecture. The germinal centers and the cords of lymphatic tissue as well as the sinuses are obliterated. Extension of the process into the capsule may occur. It must be remembered that in any given case the histologic picture in the nodes in different regions or even in different nodes in the same region may vary widely.

The typical Reed-Sternberg cell measures from 12 to 40 microns in diameter. Its shape is often irregular, and cytoplasmic processes frequently extend between neighboring cells. The nucleus, in its most characteristic form, is lobulated or multilobed. Multinucleated forms also are seen. Small forms of the Reed-Sternberg cell may occur, and in these the nucleus is round or oval. The chromatin occurs in heavy clumps, and large nucleoli are a prominent feature. The cytoplasm, which is abundant in proportion to the nucleus, varies in its staining reaction from acidophilic to basophilic, tending to be basophilic in the younger forms. In sections of tissue fixed in Zenker's fluid and stained with Mallory's phloxin-methylene blue stain, the cytoplasm often appears finely reticulated.

In sections stained for reticulum, the Reed-Sternberg cells often contain numerous silver-positive granules. In such sections these cells are often found closely applied to the reticulum fibers, and in some cases these fibers seem to pass through the cytoplasm. When stained with Penfield's modification of Hortege's silver carbonate method for microglia, the Reed-Sternberg cells tend to become impregnated, as do phagocytes of mesenchymal origin, as shown by Dunning and Furth² and as noted by us in unpublished studies. As a general rule, there is an increase in the number of reticulum fibers, which either run between single cells or enclose groups of cells. As sclerosis advances, the fibers tend to be thicker and more numerous. In a completely fibrosed node, the major portion of the intercellular substance is dense collagen.

Mitotic figures are not uncommon, and multiple mitoses are occasionally seen. Phagocytosis by Reed-Sternberg cells is uncommon. There is a strong tendency, however, for them to undergo necrobiosis. Thus, in a section of Hodgkin's granuloma scattered degenerating and pyknotic Reed-Sternberg cells are frequently found, and this feature is often an aid in diagnosis when one may be in

doubt whether true Reed-Sternberg cells are present.

In supravital preparations, the cytoplasm has a ground-glass appearance, and in some cells a delicate, finely granular rosette stained with neutral red can be seen in close proximity to the nucleus.

The exact origin of the Reed-Sternberg cells has not been proved, but we agree with those workers who believe that they are derived from the sinus endothelium and from reticulum cells. In favor of such an origin is their resemblance to these cells, especially when the Reed-Sternberg cells are small and mononuclear. A more striking resemblance is seen in the cells of Hodgkin's sarcoma and of anaplastic reticulum-cell sarcoma, in which the differential diagnosis must rest on the presence or absence of Reed-Sternberg cells. It is, of course, extremely important to differentiate normal reticulum cells and Reed-Sternberg cells. When the latter are large and typical, no difficulty should be encountered. When, however, they are small and the nuclei are not multilobed, the differential diagnosis depends on the character of the nucleus. The nucleus of a reticulum cell has finely divided, scattered chromatin and lacks a prominent nucleolus, whereas a Reed-Sternberg cell has its chromatin arranged in large masses and is characterized by one or more prominent nucleoli.

Cells occasionally confused with Reed-Sternberg cells are multinucleated plasma cells, foreign-body giant cells, Langhans giant cells, tumor giant cells and megakaryocytes. The last two may present great difficulties in differential diagnosis. Tumor giant cells, however, rarely occur singly as do Reed-Sternberg cells, and they are accompanied by other tumor cells characteristic of the neoplasm at hand. Foreign-body giant cells and Langhans cells have nuclei varying in number from several to twenty or more, and the nuclei in each of these types of cells are regular in shape, equal in size and orderly in arrangement. The chromatin is finely divided, and nucleoli are not prominent. Megakaryocytes closely resemble Reed-Sternberg cells, and given a single cell it is almost impossible to determine which of the two it is, although megakaryocytes do not have prominent nucleoli and their nuclei, although multilobed, are always single. The diagnosis must therefore depend on the picture of the section as a whole. To illustrate the difficulty of a definitive diagnosis, we refer to a nodule in the skin removed from a patient with proved myelogenous leukemia. Megakaryocytes were a prominent feature, and a number of highly competent pathologists without hesitation diagnosed the disease as Hodgkin's granuloma.

The nature and significance of the Reed-Sternberg cell is entirely obscure. It has been considered a tumor giant cell by those who consider Hodgkin's granuloma a neoplasm. In our opinion, it is probably a peculiar reactive form of the reticulum cell

in response to the agent causing the disease. In support of this conception is the cellular reaction to infection with *Bacillus mallei*, in which, as is well known, a characteristic type of giant cell is seen. It is our opinion that in like manner the Reed-Sternberg cell of Hodgkin's granuloma is the response to the unknown etiologic agent of that disease.

The number of Reed-Sternberg cells in granulomatous nodes varies widely. In some they are few in number; in others they are numerous, and may occur in groups as well as scattered. Rarely if ever are they so scarce as in paraganuloma.

In addition to the Reed-Sternberg cells, there are many other types of cells, and a pleomorphic picture is indeed characteristic of the disease. Lymphocytes are usually numerous. Plasma cells are almost constantly present, their number varying from a few to so many that a diagnosis of plasmacytoma may be entertained. One of the most outstanding features of the histologic picture of Hodgkin's granuloma, as first pointed out by Goldmann,³ is the presence of eosinophils. They are practically always present, although their number varies widely. In addition, polymorphonuclear neutrophilic leukocytes can usually be found, and are particularly prominent when the inflammatory reaction is extremely active and necrosis is present. Activity on the part of the reticulum cells, as evidenced by hyperplasia and hypertrophy, is frequent, sometimes with the formation of focal lesions resembling tubercles or Boeck's sarcoid.

In addition to the pleomorphic cellular content, two other changes are found that are characteristic of the granuloma—necrosis and fibrosis. The necrosis varies in extent from minute microscopic foci to large areas easily visible grossly. It is often of the infarct type, the cell outlines being preserved in the necrotic area. Polymorphonuclear leukocytes and reticulum cells may be found at the periphery of necrotic areas. Fibrin formation is common. Occasionally giant cells of the foreign-body type are present. The necrotic areas are eventually organized by the ingrowth of the fibroblasts of the stroma. As the processes of necrosis and fibrosis proceed, some lesions finally come to be largely composed of connective tissue, often dense and sometimes hyaline, in the interstices of which can be seen a few Reed-Sternberg cells. A high degree of fibrosis does not necessarily mean a long-standing process; on the contrary, it may represent a favorable reaction on the part of the host. Several patients when first biopsied have shown such a picture in their nodes, and their subsequent course has been relatively favorable.

As is well recognized, radiation therapy produces a high degree of sclerosis. In such nodes, however, even though markedly fibrosed, an occasional Reed-Sternberg cell can always be found.

The lesions described above may vary considerably in the different organs or tissues of any given patient. For example, some lesions present a marked inflammation with but little necrosis, others show extensive necrosis, and in still others fibrosis is the outstanding feature. The type of histologic picture depends presumably on such factors as the activity of the process, the age of the lesion and the reaction of the host to the causative agent.

Occasionally, as Sternberg¹ has pointed out, large amounts of lipid are found in the reticulum cells and in giant cells of the foreign-body type. The significance of this phenomenon is not clear, but that it may occur must be recognized in order to avoid the error of making a diagnosis of one of the diseases of disturbed lipid metabolism, such as Niemann-Pick's disease or Gaucher's disease, and of overlooking the essential granulomatous lesion.

Some authors have described another feature as not uncommon, namely, amyloid formation. In our experience this has been extremely rare.

The granulomatous form of Hodgkin's disease is frequently associated with active tuberculosis. It has been said that tuberculosis follows Hodgkin's disease like a shadow. The two processes may exist side by side in the same organ, and although grossly one may be confused with the other, the histologic characteristics of each are so definite that no difficulty in distinguishing them should be encountered.

The lymph nodes were involved at autopsy in every case in this series, and it is noteworthy that the involvement was usually widespread and of fairly uniform distribution (Table 3).

Aside from the generalized lymphadenopathy, almost every organ of the body with the exception

of the central nervous system proper may be invaded (Table 4). This fact accounts for the extraordinarily protean clinical manifestations.

The spleen is involved in a large percentage of cases. In Sternberg's¹ series it showed lesions in 80 per cent, in Terplan's⁴ in 65 per cent, and in Uddström's⁵ in 63 per cent. In our series it was involved in 75 per cent. The involved organ may be normal in size or enlarged to a marked degree. The largest spleen in this series weighed 1245 gm. and the smallest 120 gm., with an average of 480 gm. The lesions appear as circumscribed focal areas, gray to yellowish and varying in diameter from that of a miliary tubercle to a centimeter or more. As a rule, the

lesions in each spleen are of approximately the same size. Foci of necrosis similar to those seen in lymph nodes may occur. The picture produced by the focal lesions contrasting with the red color of the uninvolved portion has led to the terms "porphyry"⁶

*Multiple involvement

and "Baueruurst"⁷ spleen. The spleen has been described as the sole site of the disease.¹ In our series other organs were always involved.

Histologically, the lesions in the spleen resemble those in the lymph nodes.

The liver is frequently affected. It was involved in 38 per cent of Sternberg's cases and in 53 per cent of our series. Massive enlargement of the liver is in our experience rare. The largest liver weighed 3500 gm. In 29 of the 59 autopsied cases the organ weighed more than 1800 gm., and in 18 of these foci of Hodgkin's disease were noted. On the other hand, of the 16 livers weighing less than 1600 gm. only 4 were involved. The focal, circumscribed nodules are similar to those in the spleen, or there may be grayish streaks of diseased tissue following the distribution of the portal areas. If fibrosis is extensive, scars may be produced in such a manner that healed gummas are simulated. Some authors have described the lesions as resembling those of cirrhosis. Bile stasis due to compression of the bile ducts by the surrounding granulomatous tissue, resulting in jaundice, does occur, but it is rare. The small lesions tend to occur in the portal areas. Their histologic composition and pattern are similar to those of the lesions in lymph nodes. The large foci may cause compression and destruction of the surrounding liver tissue.

Statistics concerning the incidence of involvement of bones in Hodgkin's granuloma are unsatisfactory because of the incompleteness of examination of the osseous system.⁸ In a recent review of Hodgkin's granuloma with special reference to the involvement of the bone marrow, Steiner⁹ collected from the literature 547 autopsied cases, of which 153 (28 per cent) showed lesions of the bone marrow. In his own 14 cases, he found the marrow involved in 11 (78 per cent); it should be pointed out that he examined sixty-two bones in the 14 cases. In our series involvement of the bones occurred in 61 per cent of those cases in which the osseous system was examined. Such a figure is, however, obviously inaccurate because of the limitations in making a thorough gross and microscopic study of the bones in each case. The bones most commonly involved at autopsy in order of their frequency are the vertebrae, especially the lower thoracic and upper lumbar, and much more rarely the sternum, ribs, pelvis, femur and skull. Multiple involvement is not uncommon. The lesion may be confined to the marrow, or the process may invade and destroy the cortex, leading in the case of the vertebrae to collapse, which if extensive may result in compression of the cord, although it is surprising to what extent collapse can occur without clinical symptoms. Involvement of the bones may be metastatic or by extension from neighboring organs. Grossly the lesions appear as grayish to yellowish nodules that stand out against the remnants of the normal marrow. Although fibrosis of the involved marrow often occurs, osteosclerosis is rare.

Histologically, the lesions may be miliary in type, composed of typical granulomatous tissue with but little disturbance of the bony architecture, or extensive, causing destruction of the bony trabeculae. The process replaces the normal marrow, and at the periphery of the process great activity on the part of the hematopoietic tissue may be present. In a specimen of marrow removed by biopsy, unless a certain degree of fibrosis is present, great difficulties may be encountered in making a definite diagnosis because of the similarity of the megakaryocytes to Reed-Sternberg cells.

Versé¹⁰ estimated from a study of his own material and from the cases reported in the literature that approximately one third of the cases show involvement of the lungs. Sternberg¹ stated that of his 52 autopsied cases, 15 (29 per cent) showed such lesions. Pulmonary involvement was found in 41 per cent of our cases. The lesions may be divided into three types. In the first type, there appears a large, tumorlike mass, often involving the greater part of a lobe. Such a condition may easily be mistaken, both by x-ray and grossly at autopsy, for bronchiogenic carcinoma. In the second type, grayish streaks of diseased tissue follow the course of

in response to the agent causing the disease. In support of this conception is the cellular reaction to infection with *Bacillus mallei*, in which, as is well known, a characteristic type of giant cell is seen. It is our opinion that in like manner the Reed-Sternberg cell of Hodgkin's granuloma is the response to the unknown etiologic agent of that disease.

The number of Reed-Sternberg cells in granulomatous nodes varies widely. In some they are few in number; in others they are numerous, and may occur in groups as well as scattered. Rarely if ever are they so scarce as in paraganuloma.

In addition to the Reed-Sternberg cells, there are many other types of cells, and a pleomorphic picture is indeed characteristic of the disease. Lymphocytes are usually numerous. Plasma cells are almost constantly present, their number varying from a few to so many that a diagnosis of plasmacytoma may be entertained. One of the most outstanding features of the histologic picture of Hodgkin's granuloma, as first pointed out by Goldmann,³ is the presence of eosinophils. They are practically always present, although their number varies widely. In addition, polymorphonuclear neutrophilic leukocytes can usually be found, and are particularly prominent when the inflammatory reaction is extremely active and necrosis is present. Activity on the part of the reticulum cells, as evidenced by hyperplasia and hypertrophy, is frequent, sometimes with the formation of focal lesions resembling tubercles or Boeck's sarcoid.

In addition to the pleomorphic cellular content, two other changes are found that are characteristic of the granuloma—necrosis and fibrosis. The necrosis varies in extent from minute microscopic foci to large areas easily visible grossly. It is often of the infarct type, the cell outlines being preserved in the necrotic area. Polymorphonuclear leukocytes and reticulum cells may be found at the periphery of necrotic areas. Fibrin formation is common. Occasionally giant cells of the foreign-body type are present. The necrotic areas are eventually organized by the ingrowth of the fibroblasts of the stroma. As the processes of necrosis and fibrosis proceed, some lesions finally come to be largely composed of connective tissue, often dense and sometimes hyaline, in the interstices of which can be seen a few Reed-Sternberg cells. A high degree of fibrosis does not necessarily mean a long-standing process; on the contrary, it may represent a favorable reaction on the part of the host. Several patients when first biopsied have shown such a picture in their nodes, and their subsequent course has been relatively favorable.

As is well recognized, radiation therapy produces a high degree of sclerosis. In such nodes, however, even though markedly fibrosed, an occasional Reed-Sternberg cell can always be found.

The lesions described above may vary considerably in the different organs or tissues of any given patient. For example, some lesions present a marked inflammation with but little necrosis, others show extensive necrosis, and in still others fibrosis is the outstanding feature. The type of histologic picture depends presumably on such factors as the activity of the process, the age of the lesion and the reaction of the host to the causative agent.

Occasionally, as Sternberg¹ has pointed out, large amounts of lipoid are found in the reticulum cells and in giant cells of the foreign-body type. The significance of this phenomenon is not clear, but that it may occur must be recognized in order to avoid the error of making a diagnosis of one of the diseases of disturbed lipid metabolism, such as Niemann-Pick's disease or Gaucher's disease, and of overlooking the essential granulomatous lesion.

Some authors have described another feature as not uncommon, namely, amyloid formation. In our experience this has been extremely rare.

The granulomatous form of Hodgkin's disease is frequently associated with active tuberculosis. It has been said that tuberculosis follows Hodgkin's disease like a shadow. The two processes may exist side by side in the same organ, and although grossly one may be confused with the other, the histologic characteristics of each are so definite that no difficulty in distinguishing them should be encountered.

The lymph nodes were involved at autopsy in every case in this series, and it is noteworthy that the involvement was usually widespread and of fairly uniform distribution (Table 3).

Aside from the generalized lymphadenopathy, almost every organ of the body with the exception

TABLE 3. *Lymph Nodes Found to Be Involved at Autopsy in 59 Cases of Hodgkin's Granuloma.*

Axillary	25

of the central nervous system proper may be invaded (Table 4). This fact accounts for the extraordinarily protean clinical manifestations.

The spleen is involved in a large percentage of cases. In Sternberg's¹ series it showed lesions in 80 per cent, in Terplan's⁴ in 65 per cent, and in Uddstromer's⁵ in 63 per cent. In our series it was involved in 75 per cent. The involved organ may be normal in size or enlarged to a marked degree. The largest spleen in this series weighed 1245 gm. and the smallest 120 gm., with an average of 480 gm. The lesions appear as circumscribed focal areas, gray to yellowish and varying in diameter from that of a miliary tubercle to a centimeter or more. As a rule, the

series there was a moderate (100 to 300 cc.) serous effusion.

Twelve per cent of our cases showed involvement of the adrenal glands. In each case there had been extension of the granulomatous process from adjacent lymph nodes. Sternberg's experience was similar.

The uterus was involved microscopically in 2 of our cases.

Implication of the ovaries is rare. In 1 of our cases there was a microscopic lesion.

Sternberg¹ reports 2 cases of Hodgkin's granuloma of the thyroid gland. In 1 of our cases there were metastatic lesions in this organ.

In none of our cases was the prostate gland involved; Sternberg mentions 1 case reported in the literature. No involvement of the testis or epididymis was found, although a rare case has been described in the literature.⁴

Sternberg found granuloma of the tonsil in 5 of his 52 cases. The tonsils were enlarged and ulcerated. In none of our cases were the tonsils involved.

Rarely there is invasion of the diaphragm, breast, skin and certain other organs (Table 4).

Lesions of the central nervous system proper do not occur. Compression of the cord due to extradural masses or periosteal infiltrations of the vertebrae, however, is not infrequent. In our series no case showed such lesions at autopsy. Clinical evidence of meningeal involvement is, however, not uncommon. It should be mentioned that patients with Hodgkin's granuloma may show signs and symptoms indicating cerebral involvement, yet at autopsy no demonstrable anatomic change can be found. During life 1 of our patients had extraordinary disturbances of taste and complete anorexia, yet extremely prolonged and careful examination of the nervous system failed to reveal even a microscopic lesion.

HODGKIN'S SARCOMA

Studies of 27 autopsied cases show that Hodgkin's sarcoma usually has its origin in the retroperitoneal lymph nodes and that the lesion is characteristically invasive and destructive.

The disease was primary in the retroperitoneal nodes in 19 (70 per cent) of our cases (Table 5), and

TABLE 5. *Apparent Primary Site of Disease in Cases of Hodgkin's Sarcoma.*

Tonsil	2
Mediastinal lymph nodes	1
Para-aortic lymph nodes	1
Lung	1
Total . .	27

in all the involvement was extensive and extremely destructive. In 1 case, there was a retroperitoneal

mass of confluent lymph nodes weighing in the aggregate 1600 gm. and direct extension from these nodes to the second and third parts of the duodenum, the stomach, the head of the pancreas and the lower surface of the liver. In addition, there was compression of the common bile duct, and the aorta was buried in and partially compressed by a mass of firm, elastic nodes extending from the diaphragm to the bifurcation of the iliac vessels. In another case, a mass of lymph nodes extended along the entire length of the abdominal aorta, and the tumor infiltrated the right psoas and the right latissimus dorsi muscles, filled the entire right abdominal gutter and extended from deep within the pelvis to the twelfth right rib, which was compressed and eroded by the tumor. In a third patient, the lymphadenopathy extended from the level of the pancreas into the true pelvis.

Of the remaining 8 cases, the disease was primary in the stomach in 3, in the tonsil in 2, and in the lung, mediastinum and para-aortic nodes in 1 each. The lymph nodes were involved to a varying degree in every case, and peripheral lymphadenopathy was not uncommon (Table 6).

As might be expected, the retroperitoneal tumors resulted in many complications, such as hydro-

nephrosis, obstruction of the common bile duct and venous thrombosis due to compression by or invasion from adjacent tumor. The tendency to invade neighboring structures such as the pancreas, adrenal glands and muscle was marked.

The involved nodes were enlarged, often greatly so. In some cases their outlines could be recognized; in others the tumor had invaded the capsule, resulting in a large, irregular-shaped conglomerate mass. In consistence, the tumor may be fairly firm or soft or even practically diffuent. As a rule, however, the tissue cuts with ease, and the cut surface is grayish white to white. Areas of necrosis are not infrequent, and appear as yellowish foci that may be extremely small or very extensive.

Histologically, the tumor is composed of cells two or three times the size of a normal lymphocyte. The nucleus is usually round but may be ovoid. The majority of the cells have single spherical nuclei with prominent nucleoli, but Reed-Sternberg cells with multilobed nuclei are always seen. Their presence is necessary to establish the diagnosis of Hodgkin's sarcoma. These cells vary in number considerably from case to case, being numerous in some and few

the bronchi and usually represent an extension from affected mediastinal and tracheobronchial lymph nodes. Invasion of the walls of the bronchi with compression or even occlusion of their lumens may occur. In the third and rarest type, there are small to medium-sized circumscribed nodules scattered diffusely through the parenchyma.

Histologically, the process shows wide variations. The granulomatous tissue may fill the alveoli without destroying their walls; on the other hand, the normal structures may be entirely destroyed and replaced by the granuloma. In some cases very little connective tissue is present, the alveoli, however, containing numerous Reed-Sternberg cells. Such a cellular type of lesion may be confused with Hodgkin's sarcoma, but in the lymph nodes and other organs from the same case the usual typical granulomatous process is present and post-mortem diagnosis is not difficult. In other cases fibrosis is such an outstanding feature that the lesion resembles an organized pneumonia and careful search is necessary to detect Reed-Sternberg cells lying in the interstices of the dense connective tissue. All variations between the distinctly cellular type of process and the highly fibrotic are encountered. Cavity formation is rare and probably represents, when it does occur, a pyogenic infection of the granulomatous tissue, although in some cases, if a bronchus has been occluded, it is of the nature of a bronchiectatic abscess. The formation of lesions beneath the visceral pleura is not uncommon. The pleura is reported by Sternberg¹ as being occasionally involved. In 5 of our autopsied cases there was infiltration of the pleura without effusion, in 3 there was serous effusion only, and in 2 there was serous effusion together with infiltration of the pleura. In no case was the effusion bloody. In every case in which there was effusion the mediastinal nodes were involved.

Hodgkin's granuloma in the gastrointestinal tract may be either primary or secondary. The secondary type is usually the result of the invasion from adjacent diseased lymph nodes or other organs. In addition, secondary lesions appear as nodules in the serosa or mucosa as the result of metastasis from a generalized granulomatous process.

In our series of autopsies there were 6 cases of Hodgkin's granuloma primary in the gastrointestinal tract. Three were primary in the stomach, 1 in the ileum, 1 in the duodenum and 1 in the cecum. These figures are in essential agreement with those of Sternberg.

Grossly the gastric lesion may appear as a polypoid, tumorlike mass projecting into the lumen or as a broad-based ulcer with firm raised edges. It may lead to thickening of practically the entire wall, with marked accentuation of the normal rugae. This probably gives rise to the so-called *Gehirnaspekt* in x-ray films of the stomach, considered by some as

diagnostic of the disease. There is usually extension to neighboring lymph nodes. In rare cases only the local gastric lymph nodes are involved and no other organs or tissues show evidence of the granulomatous process.

Microscopically, the lesions in the stomach vary considerably. In some cases the process is composed of numerous Reed-Sternberg cells, many eosinophils and some lymphocytes and plasma cells, with little or no fibrosis. In other cases the granulomatous infiltration shows a moderate or a marked degree of fibrosis in addition to the characteristic cytologic elements. If there has been ulceration, the picture is further complicated by superficial necrosis and the presence of numerous polymorphonuclear leukocytes.

According to the literature,^{11,12} the intestinal granulomatous process is most frequently situated in the duodenum or the jejunum. In our series there were lesions in the lower small intestine in 4 cases, in the duodenum in 1 and the cecum in 2. The lesions appear as flat ulcers with raised, rather firm edges and with irregular, granular bases. The bowel wall may be entirely encircled. The granulomatous process also appears as plaques or tumorlike nodules that may obstruct the lumen and lead to intussusception. Cases have been reported in which erosion of an artery at the base of a granulomatous ulcer has resulted in a fatal hemorrhage. In 1 of our cases, not included in the autopsy series because there was only an incomplete post-mortem examination, rupture of the small intestine resulted in the sudden death of a patient who had appeared the day before to be in excellent condition. The possibility of such sudden deaths must always be borne in mind. Microscopically, the lesions resemble those found in the stomach.

In 9 of our autopsied cases there was marked ascites, in only 1 were there actual lesions in the peritoneum. In all cases having ascites there was involvement of the retroperitoneal nodes.

Involvement of the kidneys when the granulomatous process is widespread is not unusual. In our series it occurred in 14 per cent of the cases. There are usually small circumscribed nodules, situated especially in the cortex. We agree with Sternberg that massive lesions are distinctively rare. The histologic picture needs no comment. The ureters may be affected by extension of the process from neighboring lymph nodes.

Secondary involvement of the pancreas by extension of granulomatous lesions of the stomach, small intestine or retroperitoneal nodes is not very uncommon; it occurred in 8 of our cases. Primary involvement was not found, although it has been described in the literature.¹³

The heart muscle was not invaded in any case, but in 2 cases there were small nodules on the parietal pericardium. Terplan and Mittelbach⁴ report such lesions as being frequent. In 6 other cases in our

however, was secondarily involved in 8 cases, chiefly by metastasis. The lesions appeared as grayish-white nodules of varying size and number and were situated in the mucosa. In 2 cases the large intestine showed metastatic nodules in the mucosa, and it was invaded by extension of a primary tumor of the retroperitoneal lymph nodes in 2. In 1 case, there was a microscopic lesion of the esophagus.

It should be particularly noted that involvement of the gastrointestinal tract was not infrequently multiple and often extensive.

The pancreas was affected by tumor in 11 cases (41 per cent). In 1, the tumor was apparently metastatic from a primary lesion of the tonsil. The other cases represented direct extension from primary tumors of neighboring structures — the stomach in 3 cases and the retroperitoneal lymph nodes in 7.

The bones were examined in 22 cases. Ten of these showed tumor. In 7 cases, the vertebrae were involved, the tumor appearing as grayish nodules surrounded by red, uninvolved marrow. In 3 cases, the skull had been invaded, twice by direct extension from tumors primary in the tonsil. In the first of these, there was a pedunculated growth on the superior part of the occipital bone. The region of the sella was markedly widened, and the pituitary was involved by soft, grayish tissue. The bony structures surrounding the fossa were softened. The tumor also occupied the entire sphenoidal sinus, had eroded the surrounding sphenoidal structures and was found as well in the foramen lacrum of the petrous portion of the temporal bone. In the second case, the tumor invaded and partly destroyed the antrum and bones of the orbit on one side. In the third case, involvement of the skull was apparently metastatic from the retroperitoneal lymph nodes. In the region of the right temple there was a superficial swelling of the scalp 8 cm. in diameter. The inner table of the skull beneath this was shaggy, and the entire thickness of the bone was involved by tumor that had extended through to the dura, which was diffusely invaded. There was, however, no extension to the pia-arachnoid.

There was 1 case of involvement of the great trochanter of the femur. In 2 cases, the tumor, primary in the retroperitoneal nodes, had extended directly to the pelvic bones. In another case, the ribs showed multiple tumors secondary to a primary lesion of the para-aortic lymph nodes.

Ten cases showed involvement of the lungs at autopsy. In 1, the tumor was primary in the right lower lobe, and owing to the extensive involvement and the apparently abrupt onset, the case on admission was mistaken for one of lobar pneumonia. At autopsy, the grayish-white tumor occupied practically the whole of the lower lobe and was necrotic in its center. In 2 cases, there were scattered nodules approximately 1 cm. in diameter. Two cases grossly showed no visible tumor but it was present micro-

scopically. In the other 5 cases, the tumor had extended in from the mediastinal nodes along the bronchi.

The adrenal glands were involved in 9 cases, in each by direct extension from tumors arising in adjacent lymph nodes.

The spleen was involved in 9 cases, much less often — and far less extensively — than in Hodgkin's granuloma. In 1 case, there was direct extension from a tumor primary in the retroperitoneal lymph nodes, in the form of a yellow-white mass extending in from the hilus in a radial manner for some 6 cm. The splenic artery and vein were surrounded by the neoplasm but were not invaded by it. In 2 cases, the spleen showed only microscopic lesions. In the remaining cases there were one or more grayish-white nodules, varying in diameter from 0.1 to 1.0 cm. The involved spleens were uniformly but not greatly enlarged, the heaviest of them weighing 640 gm.

The kidneys were involved in 8 cases, in each of which the tumors were metastatic. In no case did they result from invasion from surrounding structures. In every case each kidney was involved to a similar degree. The tumor nodules were less than 1 cm. in diameter and were usually situated in the cortical region.

There was invasion by tumor of the muscles of the thoracic wall in 1 case, of the psoas muscle in 2, of the quadriceps in 1, and of the diaphragm in 1.

The central nervous system was involved in 15 per cent of the autopsies. Again one sees the sharp contrast between Hodgkin's sarcoma and Hodgkin's granuloma, in which, so far as we are aware, no involvement of the central nervous system proper has been reported. In 1 case, the tumor was primary in the paravertebral lymph nodes and had extended between the transverse process of the vertebrae from the third cervical to the eleventh dorsal, invading the dura and causing marked compression of the spinal cord in the upper cervical region. In another, there was a metastasis from a primary tumor of the retroperitoneal lymph nodes to the cerebellum. This was described as a ridge of tumor measuring 5 by 3 by 0.5 cm. and extending along the superior surface of the cerebellum. Microscopic examination revealed extensive invasion of the cerebellum well into the dentate nucleus.

The pituitary gland was involved in 3 cases. In 1 case, in which the tumor was primary in the tonsil, the gland was invaded and its normal structure obliterated. In another, it was surrounded and compressed by neoplastic tissue but was not actually invaded. In the third, microscopic examination revealed invasion of the capsule and the peripheral portion of the pars nervosa; the tumor was primary in the retroperitoneal lymph nodes.

In 3 cases, there was a moderate serous effusion into the pericardial sac, and in another a small nodule of tumor was seen in the parietal pericardium itself.

and far between in others. It is our belief that the cells with a single spherical nucleus are undifferentiated forms of the Reed-Sternberg cell. This theory is sustained by the staining reactions, the character of the chromatin and the presence of transitional forms. The cytoplasm of the tumor cells tends to stain neutrophilic or basophilic. When stained with Mallory's phloxine-methylene blue, after Zenker fixation, the cytoplasm often has a granular or reticulated appearance. Mitotic figures are usually numerous, as would be expected in a highly malignant tumor.

Apart from the tumor cells, there are usually only scattered lymphocytes and reticulum cells. The former are readily identifiable by their comparatively small size and the characteristically dense masses of chromatin. Reticulum cells are easily recognizable by their finely divided, scattered chromatin and acidophilic cytoplasm. Neutrophils, eosinophils and plasma cells are rarely found unless the tumor is located in a region exposed to complicating inflammatory infiltration. Areas of necrosis, usually of the infarct type, are not infrequent. It should be emphasized that the diagnosis of Hodgkin's sarcoma rests, in the last analysis, on the presence of Reed-Sternberg cells.

With silver stains, the reticulum fibers are usually found to be increased in number. They enclose groups of cells as well as single cells. In some cases the fibers are not only more numerous but also somewhat thickened.

The structure of the affected node is destroyed by the diffuse growth of the tumor cells. The capsule may be intact or may be extensively invaded, with extension of the neoplasm into the surrounding tissues.

Aside from the lymph nodes, the organs most frequently involved in our series were the liver, the gastrointestinal tract, the pancreas, the bones and the lungs (Table 7). The liver was involved to a greater or less degree in 16 cases (59 per cent). In 10 of these, the tumor occurred as grayish-white nodules scattered throughout the parenchyma. The size of such nodules varied widely from case to case, but in each case they were of approximately the same size. The smallest foci averaged 2 mm. in diameter and the largest measured several centimeters. In some cases only two or three tumor nodules could be found, whereas in others the organ was studded with them. In 3 cases, the tumor was situated only in the capsule. In 3 cases, there was direct extension into the liver, either from the stomach or from the retroperitoneal nodes.

On the whole, the liver was somewhat enlarged, the largest weighing 2900 gm., but the majority weighed approximately 2000 gm., and it is notable that in a number of cases the liver, although definitely involved, was no larger than normal, the few metastatic nodules being buried deep within its substance.

Various portions of the gastrointestinal tract were involved in 15 cases (55 per cent). This is in sharp contrast to the comparatively uncommon involvement of the gastrointestinal tract in Hodgkin's granuloma. In 3 cases, the disease was primary in the stomach. In one of these, the tumor involved

the posterior wall in its middle third, extending from the greater to the lesser curvature and causing an ulceration over an area measuring 12 by 4 cm. There was considerable erosion at the base of the ulcer, and extensive hemorrhage had taken place from it. The tumor was white and necrotic and cut easily. In another case, the tumor appeared as a craterlike ulcer, 4 cm. in diameter, situated 2 cm. above the pylorus. The edges of this area were elevated 0.3 to 0.4 cm. above the surrounding mucosa and were made up of moderately firm, white tissue. The center of the crater was soft and homogeneous. On section, the tumor was found to extend into the pancreas and between the vertebral bodies. In the third case, the tumor occurred at the cardiac end of the stomach and involved an area 14 cm. in diameter. From the mucosal aspect, the neoplasm appeared as a plateaulike elevation, one portion of which was cauliflowerlike, and measured 4 cm. in diameter; the surface was ulcerated and greenish gray. The tumor tissue was homogeneous, pinkish gray and soft.

In 5 other cases, the stomach was secondarily involved. In one, the tumor appeared as an ulcer; in another, as raised patches in the mucosa. In a third, the stomach wall was invaded by primary tumor of the retroperitoneal nodes. In the other two cases, the tumor produced no visible macroscopic change.

There were no tumors primary in the small or large intestine. The small intestine or duodenum,

In 3 cases, there were small metastatic nodules in the gall bladder.

In 2 cases, the thyroid gland was implicated, each time by a metastasis secondary to tumor primary in the retroperitoneal nodes. In 2 cases, metastatic nodules were found in the testes.

There was involvement by the tumor of the following organs in 1 case each: ovary, uterus, iliac vein, bladder and dura.

SUMMARY

Hodgkin's paraganuloma, characterized by the presence of Reed-Sternberg cells in the absence of necrosis or fibrosis, appears to be a disease essentially of lymph nodes. With the passage of time, it may become transformed into the more malignant Hodgkin's granuloma.

Hodgkin's granuloma, characterized by the presence of Reed-Sternberg cells, pleomorphism, eosinophils, necrosis and fibrosis, may involve any organ of the body with the exception of the central nervous system proper and is frequently widespread.

Hodgkin's sarcoma, characterized by the presence of typical Reed-Sternberg cells scattered among cells that are probably extremely anaplastic forms of Reed-Sternberg cells, behaves as a true tumor, is highly invasive and malignant and may involve any organ of the body, including the central nervous system proper.

Transitional forms of these three types of Hodgkin's disease occur, but it is essential for the understanding of the clinical features to recognize the existence of each.

PEMPHIGUS*

A Further Report on Chemical Studies of the Blood Serum and Treatment with Adrenocortical Extract, Dihydratachysterol or Vitamin D

WALTER F. LEVER, M.D.,† AND JOHN H. TALBOTT, M.D.‡

BOSTON

AS SHOWN in two recent communications,^{1,2} significant changes in the electrolyte content of the blood serum occur in patients with pemphigus vulgaris. In an attempt to correct the chemical changes, we have treated patients with pemphigus vulgaris with adrenocortical extract, dihydratachysterol or massive doses of vitamin D. In the first communication the results of treatment with adrenocortical extract in 5 patients with acute pemphigus were reported, and in the second the results of treatment with dihydratachysterol in 10 patients with chronic pemphigus.

From 1939 to 1941, 17 additional patients with pemphigus were studied and treated at the Mas-

sachusetts General Hospital. It is the purpose of this paper to report the chemical findings in the blood serum of these patients and to evaluate the effectiveness of adrenocortical extract, dihydratachysterol and massive doses of vitamin D in the treatment of this disease.

DIAGNOSIS AND PROGNOSIS

The various types of pemphigus differ not only in their clinical appearance and prognosis but also in regard to chemical changes and their response to treatment. It seems best to describe briefly the clinical appearance and the prognosis of each type before presenting the chemical data and therapeutic results. The quoted figures regarding the prognosis of the various types were obtained from a series of 62 patients with pemphigus admitted to the Massachusetts General Hospital between

*From the Dermatologic Clinic and Medical Clinic, Massachusetts General Hospital, and the Fatigue Laboratory, Harvard University

‡Associate in medicine, Harvard Medical School, and assistant physician, Massachusetts General Hospital (on leave of absence)

pital began as pemphigus erythematosus. The mortality is zero in the localized type, but in cases in which pemphigus erythematosus develops into pemphigus foliaceus or vulgaris the prognosis changes accordingly.

Pemphigus Conjunctivae

Pemphigus conjunctivae (benign mucous membrane pemphigus) always attacks the mucous membranes and, in about half the cases, the skin. The conjunctivas are nearly always affected and occasionally represent the only area of involvement. The lesions always produce scarring of the conjunctivas, frequently scarring of other mucous membranes and occasionally scarring of the skin. Pemphigus conjunctivae is an extremely chronic affection but is benign in its course. It never causes a general feeling of illness and does not end fatally.

ELECTROLYTE CONTENT OF BLOOD SERUM

The present series of 17 patients includes 3 with pemphigus vulgaris acutus, 2 with pemphigus vegetans, 6 with pemphigus vulgaris chronicus, 4 with pemphigus foliaceus and 2 with pemphigus conjunctivae. The chemical data confirm the findings previously reported.^{1,2} Significant changes in the electrolyte content of the blood serum were observed in pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus. No consistent changes were noted in pemphigus foliaceus and pemphigus conjunctivae.

In patients with pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus, the amount of sodium, chloride, calcium and protein in the blood serum was found to be reduced. Representative data of determinations at the time of admission and in the course of the disease are listed in Table 1. It is apparent that the degree of reduction usually corresponded to the severity of the clinical condition and to the amount of skin involved. In the earliest part of the disease, when only a few lesions were present, the chemical determinations usually showed normal values. For instance, patients I. D. and N. P., who at the time of admission showed only a few lesions, had normal values for nearly all constituents at that time. During the period of widespread cutaneous involvement the chemical changes were usually more pronounced in patients with pemphigus vulgaris acutus and pemphigus vegetans than in those with pemphigus vulgaris chronicus. The serum sodium was decreased in patients with pemphigus vulgaris acutus and pemphigus vegetans to values varying from 127 to 132 milliequiv. per liter, and in patients with pemphigus vulgaris chronicus to values varying from 131 to 138 milliequiv. per liter. The values for chloride closely paralleled those of the sodium. The protein was decreased to values varying from 4.6 to 5.8 gm. per 100 cc. in patients with pemphigus vulgaris acutus and pemphigus vegetans

and to 5.3 to 6.2 gm. in patients with pemphigus vulgaris chronicus. The decrease of serum calcium is less evident because most patients, soon after admission received dihydrotachysterol or massive doses of vitamin D, both of which produce a rise of the serum calcium within a short time. Nevertheless it is evident, even from the values obtained at the time of admission, that a decrease of the serum calcium is usually present in patients with pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus.

In 4 patients with pemphigus foliaceus, chemical studies revealed no significant changes except that in 1 patient the serum protein was reduced to 4.3 gm. per 100 cc. None of the patients were, when studied, in the early bullous stage, but in the chronic exfoliative stage. It may be mentioned, however, that 1 patient of the previous series² who at the time of study had been in the early bullous stage had shown a reduction of the serum sodium to 136 milliequiv. per liter. Two patients with pemphigus conjunctivae showed normal values. Similarly, 1 patient with pemphigus erythematosus studied in the previous series² had shown a normal concentration of electrolytes in the blood serum.

TREATMENT WITH ADRENOCORTICAL EXTRACT, DIHYDROTACHYSTEROL AND VITAMIN D

Administration of adrenocortical extract produces an increase of sodium in the blood serum. This hormone has a sodium-retaining action, since it increases the reabsorption of sodium in the proximal segment of the renal tubules.¹⁴ Dihydrotachysterol, as well as vitamin D, produces a rise of the calcium content of the blood serum and subsequently an increased elimination of calcium through the kidneys. The rise of the serum calcium is accomplished by increased absorption of calcium from the intestinal tract and by resorption from the bones.¹⁵ A rise of the serum protein and serum sodium usually accompanies the rise of the calcium.¹⁶

The treatment with adrenocortical extract, dihydrotachysterol and vitamin D represents an attempt to correct the chemical changes observed in patients with pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus. It was found that adrenocortical extract was the most effective drug in pemphigus vulgaris acutus and pemphigus vegetans, whereas dihydrotachysterol or massive doses of vitamin D produced the best results in pemphigus vulgaris chronicus. In several patients combined treatment with adrenocortical extract and dihydrotachysterol was used.

Adrenocortical extract was found in general to be superior to the synthetic preparation. The recommended dosage is 20 cc. a day for the first four days, and 5 to 10 cc. a day thereafter. Half the daily dose is injected intravenously and half intramuscularly. In addition, either an intravenous infusion of 1000 cc. of physiologic saline solution or 10 gm. of salt

1921 and 1936, none of whom received any of the treatments under discussion. A detailed clinical study of this group of patients has been published previously.³

There are three well-established types of pemphigus, namely, pemphigus vulgaris, pemphigus foliaceus and pemphigus vegetans. To these, two new types have been added in recent years — pemphigus conjunctivae or benign mucous-membrane pemphigus^{4, 5} and pemphigus erythematosis or Senear-Usher type of pemphigus.⁶ Furthermore, Brocq⁷ has suggested a division of pemphigus vulgaris into two types — an acute, malignant type (*pemphigus subaigu malin*) and a chronic, benign type. The septic (acute or butcher's) pemphigus, however, is no longer regarded as a disease entity. As stated elsewhere,⁸ it is believed that cases that in the past have been reported with this diagnosis can be classified as bullous impetigo, severe erythema multiforme or pemphigus vulgaris acutus.

Clinical study of the patients with pemphigus at the Massachusetts General Hospital has shown that separate consideration of these three additional types is justified.

Acute Pemphigus Vulgaris Acutus

Descriptions of pemphigus vulgaris acutus (*pemphigus subaigu malin* or malignant pemphigus vulgaris) have been given by Brocq,⁷ Lane and Lambert⁹ and Pelagatti.¹⁰ We^{11, 12} have discussed the clinical picture in two recent communications. The bullas are usually small and flaccid and break easily. Occasionally no bullas form on the skin and the epithelium merely slides off, leaving erosions, which tend to enlarge as the epithelium becomes detached at the periphery. By peripheral extension and confluence of the erosions large areas of the body may become denuded. The large erosions, which are the most important clinical sign of this type of pemphigus, show little tendency to heal. The oral mucosa is involved in nearly all cases. The mouth is frequently the site of the first lesions. The oral involvement, if present, is usually severe. Large denuded areas may develop in the mouth, just as on the skin, by peripheral extension of the erosions. In the severest stage almost the entire oral mucosa may be transformed into a single large, eroded surface. Frequently the lesions extend to the vermilion border of the lips, and hemorrhagic crusts form on the lips.

A large percentage of the patients are Jewish. The mortality among 22 patients seen at the Massachusetts General Hospital between 1921 and 1936 was 100 per cent. The average duration of the disease was seven and a half months.

Pemphigus Vegetans

As stated in a previous communication,¹¹ pemphigus vegetans resembles pemphigus vulgaris acutus in every respect except the vegetations

that form secondarily on the erosions. The prognosis is grave, although not quite so hopeless as that in acute pemphigus vulgaris. Fruhwald,¹³ in reviewing the outcome of 147 cases of pemphigus vegetans as reported in the literature, found the mortality to be 73 per cent. He believed, however, that some additional patients might have died subsequent to the time of publication.

Pemphigus Vulgaris Chronicus

In pemphigus vulgaris chronicus the bullas are usually tense and may attain considerable size, but do not break so easily as in the acute form of the disease. The erosions at the site of broken blisters do not extend to the periphery. The tendency of the erosions to heal is well pronounced. This form rarely starts in the mouth, and only about half the cases ever show involvement of the oral mucosa. The appearance of the oral lesions corresponds to that of the cutaneous lesions. One can frequently see intact blisters in the mouth, because they do not break easily. They are usually small, and the erosions at the site of broken blisters do not tend to increase in size, so that the oral involvement is never so extensive as in pemphigus vulgaris acutus.

Pemphigus vulgaris chronicus is apparently rare among Jews, since none of the patients with this form seen at the Massachusetts General Hospital since 1921 belonged to the Jewish race. The mortality in 16 patients seen between 1921 and 1936 was 50 per cent.

Pemphigus Foliaceus

Pemphigus foliaceus shows bullas only in the early stage and gradually assumes the appearance of a generalized exfoliative dermatitis, from which it is; however, easily differentiated by the presence of a positive Nikolsky sign. Oral lesions are absent. The mortality rate in the 14 patients with pemphigus foliaceus seen between 1921 and 1936 was 43 per cent. In those who survive, this disease may become extremely chronic. In 4 of the 14 patients who were first seen between 1921 and 1936, the disease has by now persisted for more than ten years. Age appears to be an important factor in the prognosis. In the patients who acquired pemphigus foliaceus before the age of thirty the mortality rate was 13 per cent; in those who acquired it at a later age it was 83 per cent.

Pemphigus Erythematosis

Many cases of pemphigus erythematosis (Senear-Usher type of pemphigus) may be regarded, as Gray¹⁴ has suggested, as a localized form of pemphigus foliaceus that may remain localized or change into pemphigus foliaceus. This concept cannot, however, be applied to all cases, since several reports have appeared in which pemphigus vulgaris subsequently developed. Three cases of pemphigus foliaceus seen at the Massachusetts General Hos-

pital began as pemphigus erythematosus. The mortality is zero in the localized type, but in cases in which pemphigus erythematosus develops into pemphigus foliaceus or vulgaris the prognosis changes accordingly.

Pemphigus Conjunctivae

Pemphigus conjunctivae (benign mucous membrane pemphigus) always attacks the mucous membranes and, in about half the cases, the skin. The conjunctivas are nearly always affected and occasionally represent the only area of involvement. The lesions always produce scarring of the conjunctivas, frequently scarring of other mucous membranes and occasionally scarring of the skin. Pemphigus conjunctivae is an extremely chronic affection but is benign in its course. It never causes a general feeling of illness and does not end fatally.

ELECTROLYTE CONTENT OF BLOOD SERUM

The present series of 17 patients includes 3 with pemphigus vulgaris acutus, 2 with pemphigus vegetans, 6 with pemphigus vulgaris chronicus, 4 with pemphigus foliaceus and 2 with pemphigus conjunctivae. The chemical data confirm the findings previously reported.^{1,2} Significant changes in the electrolyte content of the blood serum were observed in pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus. No consistent changes were noted in pemphigus foliaceus and pemphigus conjunctivae.

In patients with pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus, the amount of sodium, chloride, calcium and protein in the blood serum was found to be reduced. Representative data of determinations at the time of admission and in the course of the disease are listed in Table 1. It is apparent that the degree of reduction usually corresponded to the severity of the clinical condition and to the amount of skin involved. In the earliest part of the disease, when only a few lesions were present, the chemical determinations usually showed normal values. For instance, patients I. D. and N. P., who at the time of admission showed only a few lesions, had normal values for nearly all constituents at that time. During the period of widespread cutaneous involvement the chemical changes were usually more pronounced in patients with pemphigus vulgaris acutus and pemphigus vegetans than in those with pemphigus vulgaris chronicus. The serum sodium was decreased in patients with pemphigus vulgaris acutus and pemphigus vegetans to values varying from 127 to 132 milliequiv. per liter, and in patients with pemphigus vulgaris chronicus to values varying from 131 to 138 milliequiv. per liter. The values for chloride closely paralleled those of the sodium. The protein was decreased to values varying from 4.6 to 5.8 gm. per 100 cc. in patients with pemphigus vulgaris acutus and pemphigus vegetans

and to 5.3 to 6.2 gm. in patients with pemphigus vulgaris chronicus. The decrease of serum calcium is less evident because most patients, soon after admission received dihydrotachysterol or massive doses of vitamin D, both of which produce a rise of the serum calcium within a short time. Nevertheless it is evident, even from the values obtained at the time of admission, that a decrease of the serum calcium is usually present in patients with pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus.

In 4 patients with pemphigus foliaceus, chemical studies revealed no significant changes except that in 1 patient the serum protein was reduced to 4.3 gm. per 100 cc. None of the patients were, when studied, in the early bullous stage, but in the chronic exfoliative stage. It may be mentioned, however, that 1 patient of the previous series² who at the time of study had been in the early bullous stage had shown a reduction of the serum sodium to 136 milliequiv. per liter. Two patients with pemphigus conjunctivae showed normal values. Similarly, 1 patient with pemphigus erythematosus studied in the previous series² had shown a normal concentration of electrolytes in the blood serum.

TREATMENT WITH ADRENOCORTICAL EXTRACT, DIHYDROTACHYSTEROL AND VITAMIN D

Administration of adrenocortical extract produces an increase of sodium in the blood serum. This hormone has a sodium-retaining action, since it increases the reabsorption of sodium in the proximal segment of the renal tubules.¹⁴ Dihydrotachysterol, as well as vitamin D, produces a rise of the calcium content of the blood serum and subsequently an increased elimination of calcium through the kidneys. The rise of the serum calcium is accomplished by increased absorption of calcium from the intestinal tract and by resorption from the bones.¹⁵ A rise of the serum protein and serum sodium usually accompanies the rise of the calcium.¹⁶

The treatment with adrenocortical extract, dihydrotachysterol and vitamin D represents an attempt to correct the chemical changes observed in patients with pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus. It was found that adrenocortical extract was the most effective drug in pemphigus vulgaris acutus and pemphigus vegetans, whereas dihydrotachysterol or massive doses of vitamin D produced the best results in pemphigus vulgaris chronicus. In several patients combined treatment with adrenocortical extract and dihydrotachysterol was used.

Adrenocortical extract was found in general to be superior to the synthetic preparation. The recommended dosage is 20 cc. a day for the first four days, and 5 to 10 cc. a day thereafter. Half the daily dose is injected intravenously and half intramuscularly. In addition, either an intravenous infusion of 1000 cc. of physiologic saline solution or 10 gm. of salt

in enteric-coated capsules is given daily. If the synthetic drug is used, the daily dosage recommended is 3 cc. intramuscularly during the first week, and 1 or 2 cc. thereafter. One thousand cubic centimeters of normal saline or 10 gm. of salt is also given daily. No toxic effects were observed as a result of this plan of treatment.

Dihydrotachysterol and vitamin D, which have a similar action on the calcium metabolism of the body, were found to possess the same degree of effectiveness. The optimal therapeutic effect was observed when the concentration of the serum calcium was raised above the normal level of 5 milliequiv. to a concentration of 6.5 to 7.5 milliequiv. per liter. This effect was usually accomplished by giving 10 or 15 cc. of dihydrotachysterol for seven to fourteen days. The serum calcium was maintained at this level in most cases by giving 3 to 5 cc. of dihydrotachysterol a day. Seventy-five thousand units of vitamin D was found to correspond approximately to 1 cc. of dihydrotachysterol in their calcium-raising effect. The two dangers of this treatment—namely, hypercalcemic coma with subsequent circulatory collapse and renal damage through mechanical obstruction of the tubules by calcium deposits—have been discussed in detail in the previous paper.² It had been stated that dihydrotachysterol and massive doses of vitamin D must be given with great circumspection to persons older than sixty and that it is contraindicated in patients with demonstrable renal insufficiency. Careful control of the level of calcium and non-protein nitrogen is required. These determinations should be carried out twice a week during the first few weeks and later once a week.

Administration of dihydrotachysterol or vitamin D in the recommended doses produced a rise of the calcium level above normal in all patients so treated (table 1). The rise usually began within one week. The effect of adrenocortical extract was less uniform. The rise of the sodium occurred often only after several weeks of treatment and, before the rise occurred, a continued decrease of the sodium was occasionally noted when the condition of the skin became worse.

Results

Treatment with adrenocortical extract, dihydrotachysterol or massive doses of vitamin D produced some favorable results in pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus, the three types of pemphigus in which a reduction of the serum sodium, chloride, calcium and protein occurs. The results of treatment in pemphigus foliaceus, pemphigus erythematous and pemphigus conjunctivae, in which no significant chemical changes are observed, were in general disappointing.

Fifteen case reports of patients treated with adrenocortical extract or dihydrotachysterol were

given in the two previous communications.^{1,2} For this reason, no case histories will be given here but the cases of each type will be discussed collectively.

Pemphigus vulgaris acutus. A total of 7 patients with pemphigus vulgaris acutus received treatment with adrenocortical extract, dihydrotachysterol or massive doses of vitamin D. Four of them died of pemphigus and 3 survived, a mortality of 57 per cent, compared with 100 per cent in 22 patients admitted between 1921 and 1936 who did not receive this treatment.

The course of 4 cases under treatment with adrenocortical extract was reported in detail in the previous communication.¹ Two patients died of pemphigus, one of them, however, only after he had a complete, although short, remission. Two patients were reported as cured. One of them is still living and well, and the other has since died from cerebral hemorrhages without having had any more lesions of pemphigus.

Between 1939 and 1941, 5 patients with pemphigus vulgaris acutus were treated. Two of them died after less than two weeks' treatment. These cases have been excluded from statistical consideration, because death occurred before treatment could have taken full effect. Of the remaining 3 patients, 2 died of pemphigus after a prolonged period of treatment and 1 is living. The 2 patients who died after prolonged treatment first seemed to respond to the treatment in that they had a complete remission lasting several weeks, but then relapsed in spite of continued treatment. The 1 living patient has been free from lesions for three years. The improvement that was observed in all 3 patients of the present series began three to six weeks following institution of treatment.

The question arises whether the observed remissions might not have been spontaneous. This is possible, but spontaneous complete remissions in pemphigus vulgaris acutus are rare and were, for instance, not observed in any of the 22 cases of pemphigus vulgaris acutus seen between 1921 and 1936. An incidence of 6 complete remissions in the 7 cases of both series seems significant.

Two of the 3 patients of the present series were treated with both adrenocortical extract and dihydrotachysterol or vitamin D and 1 with vitamin D alone. The surviving patient received both types of treatment. It seems that in acute pemphigus vulgaris it is advisable to use both types of treatment.

Pemphigus vegetans. Three patients with pemphigus vegetans were treated. Two of them died of pemphigus and 1 survived.

The course of 1 case treated with adrenocortical extract was reported in the previous communication.¹ The patient died after having had a complete remission lasting for five weeks.

The present series includes 2 patients with pemphigus vegetans. One died after having undergone

a complete remission lasting two weeks; the other is living. Improvement was observed in both patients approximately two to three weeks after treatment was begun. The surviving patient has had a few lesions in the anogenital region and in the oral cavity most of the time since her first discharge three years ago. On two occasions she had moderately severe relapses, which, however, subsided within a few weeks after resumption of treatment.

In spite of the fact that 2 of the 3 patients of both series finally succumbed, it appears significant that

no lesions of pemphigus present; the other 4 patients are living. The patient who died of pemphigus showed a satisfactory response so far as the cutaneous lesions were concerned, but had become extremely weak and anemic, death occurring when hypostatic bronchopneumonia developed. At the time of exitus only a few scattered, small bullas were present. Of the 4 living patients 3 are free from lesions and 1 occasionally develops a few lesions but is otherwise well. Two of the 3 patients who are free from lesions had a mild relapse after

all 3 patients showed complete remissions under treatment.

The surviving patient of the present series received treatment with adrenocortical extract, and the other received dihydratichysterol. It is believed that, just as in pemphigus vulgaris acutus, the combined treatment with adrenocortical extract and dihydratichysterol or vitamin D is advisable.

Pemphigus vulgaris chronicus. Fourteen patients with pemphigus vulgaris chronicus were treated.

treatment had been discontinued but recovered when treatment was resumed.

In 3 of the 6 patients improvement began within two weeks, in the other 3 patients after three to six weeks of treatment. Three of the 4 patients who showed complete healing were free from active lesions six weeks after treatment was begun, but 1 patient ceased forming lesions only after three months of treatment.

The treatment in 4 of the 6 cases of the present series consisted of dihydratichysterol in the begin-

<i>Pemphigus conjunctivae</i>	2	0	0	10	0	0

Two of them died and 12 survived, a mortality of 14 per cent, compared with 50 per cent in the 16 patients not so treated.

Eight of the 10 patients reported previously² as having been treated with dihydratichysterol had pemphigus vulgaris chronicus. One of them was reported to have died from pemphigus, 4 as having died from other diseases with no lesions of pemphigus present, and 3 as living. These 3 patients are still living and well and have had no further treatment.

Six patients with pemphigus vulgaris chronicus were treated between 1939 and 1941. One died of pemphigus and 1 from cardiovascular disease with

ning and vitamin D later. In 1 of these patients adrenocortical extract was also given for seven weeks because of an extremely low serum sodium (131 milliequiv. per liter). Two patients received only vitamin D. Dihydratichysterol and vitamin D seemed to possess the same degree of effectiveness when given in corresponding doses.

Pemphigus foliaceus. The previous report concerning treatment of chronic pemphigus with dihydratichysterol² included 1 case of pemphigus foliaceus. This patient had come under treatment in the early stage of the disease when bullas were still present. The recovery under treatment with dihydratichysterol was slow but satisfactory. The

in enteric-coated capsules is given daily. If the synthetic drug is used, the daily dosage recommended is 3 cc. intramuscularly during the first week, and 1 or 2 cc. thereafter. One thousand cubic centimeters of normal saline or 10 gm. of salt is also given daily. No toxic effects were observed as a result of this plan of treatment.

Dihydrotachysterol and vitamin D, which have a similar action on the calcium metabolism of the body, were found to possess the same degree of effectiveness. The optimal therapeutic effect was observed when the concentration of the serum calcium was raised above the normal level of 5 milliequiv. to a concentration of 6.5 to 7.5 milliequiv. per liter. This effect was usually accomplished by giving 10 or 15 cc. of dihydrotachysterol for seven to fourteen days. The serum calcium was maintained at this level in most cases by giving 3 to 5 cc. of dihydrotachysterol a day. Seventy-five thousand units of vitamin D was found to correspond approximately to 1 cc. of dihydrotachysterol in their calcium-raising effect. The two dangers of this treatment—namely, hypercalcemic coma with subsequent circulatory collapse and renal damage through mechanical obstruction of the tubules by calcium deposits—have been discussed in detail in the previous paper.² It had been stated that dihydrotachysterol and massive doses of vitamin D must be given with great circumspection to persons older than sixty and that it is contraindicated in patients with demonstrable renal insufficiency. Careful control of the level of calcium and non-protein nitrogen is required. These determinations should be carried out twice a week during the first few weeks and later once a week.

Administration of dihydrotachysterol or vitamin D in the recommended doses produced a rise of the calcium level above normal in all patients so treated (Table 1). The rise usually began within one week. The effect of adrenocortical extract was less uniform. The rise of the sodium occurred often only after several weeks of treatment and, before the rise occurred, a continued decrease of the sodium was occasionally noted when the condition of the skin became worse.

Results

Treatment with adrenocortical extract, dihydrotachysterol or massive doses of vitamin D produced some favorable results in pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus, the three types of pemphigus in which a reduction of the serum sodium, chloride, calcium and protein occurs. The results of treatment in pemphigus foliaceus, pemphigus erythematosus and pemphigus conjunctivae, in which no significant chemical changes are observed, were in general disappointing.

Fifteen case reports of patients treated with adrenocortical extract or dihydrotachysterol were

given in the two previous communications.^{1,2} For this reason, no case histories will be given here but the cases of each type will be discussed collectively.

Pemphigus vulgaris acutus. A total of 7 patients with pemphigus vulgaris acutus received treatment with adrenocortical extract, dihydrotachysterol or massive doses of vitamin D. Four of them died of pemphigus and 3 survived, a mortality of 57 per cent, compared with 100 per cent in 22 patients admitted between 1921 and 1936 who did not receive this treatment.

The course of 4 cases under treatment with adrenocortical extract was reported in detail in the previous communication.¹ Two patients died of pemphigus, one of them, however, only after he had a complete, although short, remission. Two patients were reported as cured. One of them is still living and well, and the other has since died from cerebral hemorrhages without having had any more lesions of pemphigus.

Between 1939 and 1941, 5 patients with pemphigus vulgaris acutus were treated. Two of them died after less than two weeks' treatment. These cases have been excluded from statistical consideration, because death occurred before treatment could have taken full effect. Of the remaining 3 patients, 2 died of pemphigus after a prolonged period of treatment and 1 is living. The 2 patients who died after prolonged treatment first seemed to respond to the treatment in that they had a complete remission lasting several weeks, but then relapsed in spite of continued treatment. The 1 living patient has been free from lesions for three years. The improvement that was observed in all 3 patients of the present series began three to six weeks following institution of treatment.

The question arises whether the observed remissions might not have been spontaneous. This is possible, but spontaneous complete remissions in pemphigus vulgaris acutus are rare and were, for instance, not observed in any of the 22 cases of pemphigus vulgaris acutus seen between 1921 and 1936. An incidence of 6 complete remissions in the 7 cases of both series seems significant.

Two of the 3 patients of the present series were treated with both adrenocortical extract and dihydrotachysterol or vitamin D and 1 with vitamin D alone. The surviving patient received both types of treatment. It seems that in acute pemphigus vulgaris it is advisable to use both types of treatment.

Pemphigus vegetans. Three patients with pemphigus vegetans were treated. Two of them died of pemphigus and 1 survived.

The course of 1 case treated with adrenocortical extract was reported in the previous communication.¹ The patient died after having had a complete remission lasting for five weeks.

The present series includes 2 patients with pemphigus vegetans. One died after having undergone

MEDICAL PROGRESS

DISEASES OF THE VEINS

JOHN HOMANS, M.D.*

BOSTON

VENOUS THROMBOSIS AND PULMONARY EMBOLISM

PATHOLOGISTS have long recognized the frequency of thrombosis in the deep veins of the lower legs. Only occasionally have impressive observations been reported; yet when post-mortem examinations have been made with the clinical problem in view, it has been discovered that following death from a great variety of causes, deep-venous thrombosis has been found below the knees in at least 25 per cent of all the subjects investigated. In some reports the percentage is much higher. A good example of a study of this sort, previously quoted in progress notes made by me in 1942, is that of Hunter, Sneed, Robertson and Snyder.¹ They undertook to discover the percentage of venous thrombosis of the lower leg in patients from a charity hospital, from a state psychopathic institution and from two private hospitals, believing, very naturally, that the background of the patient and the nature of his illness might influence the frequency of the disease. Needless to say, they were looking for the quiet type, — the so-called "phlebothrombosis" — which is necessarily little noticed clinically and that is recognized today as the usual source of pulmonary embolism.

They found thrombi of various ages to be present in 52.7 per cent of the 351 unselected middle-aged and elderly patients who had been forced to bed for varying periods before death. They studied microscopically 209 pairs of soleus and gastrocnemius muscles. Inasmuch as pulmonary embolism had been responsible for only 3.1 per cent of all the deaths in their series, it is evident that much of the thrombosis had either healed or was a terminal manifestation, not having advanced upward beyond the lower legs. This is in accordance with still earlier pathological observations of Rossle,² who found what may be described as terminal thrombosis in 25 per cent of all cases, and of Neumann,³ who reported isolated venous thrombosis confined to the

parts below the knees in 29 per cent of the bodies investigated. It appears that in the study of Hunter and his associates the percentage of lower-leg thrombosis in the various hospitals was 59 per cent in the charity hospital, 49 per cent in the state psychopathic institution and 40 to 42 per cent in the two private hospitals. From such figures as these one is justified in concluding that confinement to bed, whatever its cause, tends to lead to thrombosis in the veins of the legs and that the more enfeebled patients show a higher percentage of disease than do the better preserved ones. Indeed, it has been too little recognized that serious illnesses, including those of the heart itself, are frequently complicated by quiet thrombosis and fairly often terminated by pulmonary embolism. Rossle,² in the study of his relatively small series, remarks that the death of the patient cuts off the development of many low processes that would otherwise have spread upward into the femoral vein. One need not follow this line further, but need only recognize that here is a background against which observations made during life may be interpreted.

An important aspect of deep venous thrombosis is the causal relation of trauma, in the broad sense. One must think of surgical operations — unfortunately — in this connection, especially in patients suffering from cancer or other debilitating diseases, but fracture of any bone of the lower limbs, including those of the feet, whatever the form of fixation used, must be regarded as almost as important a cause of thrombosis and pulmonary embolism. My⁴ first experiences with actual or threatened embolism arose from metatarsal fractures in vigorous middle-aged persons. Just where post-partum thrombosis belongs in the picture is difficult to say. There is reason, of course, to suspect an entirely pelvic origin, but since there is nothing about a "milk leg" that is essentially different from any other thrombophlebitis, the lower leg should, for the moment, be regarded as its chief source.

How does such thrombosis arise? Wright^{5, 6} offers a reasonable explanation for what may be at least

*Clinical professor of surgery, Tufts College Medical School, clinical professor of surgery, emeritus, Harvard Medical School, consultant in surgery, Peter Bent Brigham Hospital and Joseph H. Pratt Diagnostic Hospital

patient has had occasionally during the last four years a few erythematous lesions on the skin, but the Nikolsky sign has been negative and he has been able to do heavy labor.

Four more patients with pemphigus foliaceus were treated between 1939 and 1941. All came under treatment at a time when bullas were no longer present. They presented the appearance of a generalized exfoliative dermatitis. All of them were treated with either dihydrotachysterol or massive doses of vitamin D. None of them showed improvement. Two died and 2 are living.

Pemphigus erythematosis. One case of pemphigus erythematosis treated with dihydrotachysterol was included in the previous report.² The patient had shown slow improvement. At present the patient still has a few scattered lesions.

Pemphigus conjunctivae. Two patients with pemphigus conjunctivae were treated for an extended period with massive doses of vitamin D. Both had conjunctival and oral lesions. No improvement was noted in either case.

DISCUSSION

No etiologic significance can be attached to the chemical changes observed in pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus. In the first place, during the earliest part of the disease when there were only a few lesions present the chemical determinations usually showed normal values. Furthermore, 3 of the 4 patients who died of pemphigus had at the time of death abnormally high sodium concentrations and 3 had abnormally high calcium concentrations in the blood serum. Although the high values can be attributed to the treatment, the fact that they were encountered at the time of death excludes sodium or calcium deficiency as a primary factor in the cause of the disease. The reduction of the serum sodium, chloride, calcium and protein is therefore regarded as a secondary symptom produced by the disease. It is possible that the chemical changes are due to the loss of plasma through the cutaneous lesions and the resulting osmotic changes. Damage to the adrenal glands, as observed in 2 patients with pemphigus vulgaris acutus and reported in one of the previous communications,¹ may be a factor of importance in some cases.

The favorable results obtained by treatment with adrenocortical extract, dihydrotachysterol or massive doses of vitamin D in some cases of pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus are apparently based on the tendency of these drugs to correct the chemical changes that occur in these forms of pemphigus. Since the chemical changes are secondary symptoms produced by the disease, the treatment is regarded as merely symptomatic. Although its limitations are fully realized, it is believed that it may well be

tried in patients with pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus, not only as a measure for correction but also as a means for prevention of the chemical changes. Whether or not treatment with dihydrotachysterol or massive doses of vitamin D is of any value in the early, bullous stage of pemphigus foliaceus is a question that only further investigation can decide.

SUMMARY

Six types of pemphigus are recognized — pemphigus vulgaris acutus (Brocq's *pemphigus subaigu malin*), pemphigus vegetans, pemphigus vulgaris chronicus, pemphigus foliaceus, pemphigus erythematosis (Senear-Usher type of pemphigus) and pemphigus conjunctivae.

In pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus, the amount of sodium, chloride, calcium and protein in the blood serum was found to be reduced. These changes were more pronounced in pemphigus vulgaris acutus and pemphigus vegetans than in pemphigus vulgaris chronicus. The degree of reduction usually corresponded to the severity of the clinical condition and the amount of skin involved.

No etiologic significance can be attached to the chemical changes. They are regarded as a secondary symptom produced by the disease.

Thirty-two patients with pemphigus were treated with adrenocortical extract, dihydrotachysterol or massive doses of vitamin D. Encouraging results were obtained in several patients with pemphigus vulgaris acutus, pemphigus vegetans and pemphigus vulgaris chronicus. The results of treatment in patients with pemphigus foliaceus, pemphigus erythematosis and pemphigus conjunctivae were in general disappointing.

The treatment tends to correct the reduction of sodium, chloride, calcium and protein encountered in such patients. Since it is believed that the chemical changes are secondary symptoms produced by the disease, the treatment is merely symptomatic.

ferently. Welch and Faxon⁹ seem to think that since the diseases merge into one another, the distinction between them is not of fundamental importance. All agree, however, that from the solid, inflammatory thrombus, pulmonary emboli are very unlikely to be detached, whereas with the quiet, nonobstructive one, much more like a soft clot, embolism is always threatened. Ochsner and DeBaKey point out the wisdom of relaxing the various sorts of vasoconstriction in thrombophlebitis by a lumbar sympathetic block, and what may be called "the Boston school," including Welch and Faxon,⁹ Welch, Faxon and McGahey,¹⁴ Allen, Linton and Donaldson,¹⁵ Fine and Sears,¹⁶ Fine, Frank and Starr,¹⁷ myself and others, has long advocated, for the quiet phlebothrombosis, division of the principal vein of the limb or limbs affected, with the idea of halting the process and of preventing pulmonary embolism. Hence the importance of distinguishing between the two types — or, it may be, stages — is obvious.

DIAGNOSIS

In their recent paper, Allen, Linton and Donaldson¹⁵ make the point that if one could see a four-hourly temperature chart of every patient subject to the possibility of venous thrombosis in the legs, there would be evident, as the earliest sign of embolic detachment, a rise of pulse rate and temperature. I myself believe that entirely apart from gross embolism, a soft propagating thrombus often gives off small fragments that, without causing outspoken signs, disturb the pulmonary circulation, causing an increased respiratory and cardiac rate. One notices, for instance, after effective interruption of the principal vein or veins proximal to the thrombus, an immediate easing of the clinical situation, much more definite than might come, for example, through relief of the patient's anxiety, if such were present. Thrombosis itself need occasion no rise whatever, and there is often an interval of hours or days between the rise and the first thoracic symptoms of gross embolism. The trouble with this observation is that it is usually made in retrospect, and of course there are other causes of an elevation in the pulse rate and temperature curve besides the onset of embolism. Observation of the chart should be regarded as of the very first importance, however, and, along with the various physical signs in the legs themselves, is extraordinarily helpful. DeTakats¹⁸ takes this view, saying that a slight rise of temperature and a persistently elevated pulse rate, without apparent cause, after the fourth or fifth post-operative day should make one seek other signs of latent thrombosis. Among other things, he is interested in the skin temperature and soreness to touch of the sole of the foot. Allen and his associates¹⁵ mention in the order of their frequency a number of positive findings. In their series, some degree of swelling was found in 67 per cent of the

237 cases examined, tenderness was found in 61 per cent of 231 cases investigated with that finding in view, and in 139 cases examined for what they called "Homans's sign," — I prefer to call it the dorsiflexion sign, — this was found to be present in 42 per cent. I regard this dorsiflexion sign as having a greater degree of importance than would be judged from this analysis. Actually, dorsiflexion of the feet is intended to bring out, on the side of the venous thrombosis, some degree of irritability of the posterior muscles, the soleus and gastrocnemius. Discomfort need have no part in this reaction. Dorsiflexion may be less complete in response to an equal degree of upward pressure on the affected side as compared with the normal, or the patient may involuntarily flex the knee as the forefoot is forced upward, to release the tension on the posterior muscles. If one looks on the dorsiflexion sign as evidence of even the faintest irritability of the posterior muscles, — the early stage of the thrombosis occurring within and about them, — the sign will probably be found present more frequently than either tenderness or swelling.

Pulmonary embolism. As Allen and his associates note, pulmonary embolism is the first evidence of deep venous thrombosis in the lower limbs in a considerable proportion of cases — 41 per cent in their series. This does not mean that signs in the legs may not have been present but that none have been observed. It is true, however, that in a surprising number of persons some sort of thoracic distress or pain, or breathlessness, or cough gives the only hint that a quiet thrombosis in the legs is going on. This is in accordance with the general rule recognized by all those familiar with this subject; namely, that the more silent and less inflammatory the thrombosis in the lower limbs, the likelier is the process to cause pulmonary embolism. An outspoken thrombophlebitis, being an adherent, occluding process, rarely occasions any such accident. The quietest sort of thrombosis may occupy only a small stretch of vein among the calf muscles yet give rise to a long, hanging, potentially fatal thrombus.

Although it is not properly a subject of these notes, attention is called here to the importance of the electrocardiogram in the diagnosis of pulmonary embolism. As early as 1935, McGinn and White¹⁹ described cor pulmonale and its characteristic physical and electrocardiographic signs. In a recent communication, Murnaghan, McGinn and White²⁰ develop further the whole subject of the electrocardiographic diagnosis of pulmonary embolism, citing a number of clinical reports. Among their series of 10 cases were 3 of pulmonary embolism following bone injuries in women over sixty, 3 of postoperative embolism, 2 of these occurring in the third decade, and 3 in which the patients presented pulmonary symptoms from the beginning of their illness. Nine of these 10 patients had two or more attacks of infarction, the tenth only one. In 3 cases,

a contributing factor. He finds that the blood-platelet count rises following childbirth and surgical operations. The rise begins on the fourth day and reaches its maximum on the twelfth, falling back to normal on the twenty-first. There is a rough correspondence here with the clinical onset of thrombosis. But platelets do more than multiply. According to Wright, they become "sticky." Adhesiveness increases as the thrombocytes grow in number and is attributed to the quality of the platelets rather than to a change in the serum. Such phenomena have not been invoked in explanation of nontraumatic forms of venous thrombosis; that is, those that so frequently complicate serious illness, as well as the less common ones of active life. They may not perhaps be of great significance and they are certainly not fundamental. Even if invoked to explain postoperative thrombosis, they can hardly apply before the fourth day; and Newburger,^{7*} in a recent collective review of early postoperative walking, notes that since those physicians who got their patients out of bed on the third day still encountered thrombosis and embolism, thrombosis must often begin earlier—a suggestion in which I concur. Probably the moment of onset varies considerably and one must continue to regard life in bed, the reclining position, abdominal distention, enfeeblement of the circulation and elevation of venous pressure in the lower limbs, perhaps combined with muscular relaxation and atrophy of the legs, as of first importance.

A recent development, stimulated by White's⁸ observations on patients suffering from, or thought to be suffering from, cardiac or pulmonary disease, is the realization that quiet thrombosis may take place not only in persons already incapacitated by a cardiac disorder of some sort but in others apparently leading an active and sufficiently normal life. Such persons may even be young,—that is, in their teens,—although pulmonary embolism in the first four or five decades is unusual. That fatal embolism seldom occurs before the age of fifty was brought out by Welch and Faxon⁹ in their study of patients, mainly postoperative, at the Massachusetts General Hospital in 1941. I myself,¹⁰ dealing with a necessarily small ambulatory group, some of whom, because of repeated nonfatal embolism, had been falsely accused of suffering from angina or disease of their coronary arteries, have found the same thing to be true. Quiet venous thrombosis in the deep veins of the lower legs may take place at any age, although increasing in frequency with the years, but a fatal accident before the fiftieth year is rare. It is remarkable how often pulmonary embolism may occur and recur in ambulatory patients and how likely such persons are to be suspected of cardiac or pulmonary ailments rather than of

embolism from an unnoticed deep thrombosis in the lower legs. It is not even necessary that the patient should have suffered from an old thrombophlebitis now canalized. The veins of the legs may previously have been, so far as one can learn, entirely normal, giving no excuse whatever for a thrombotic process. As will appear later, the patient of fifty or over who suffers from an arterial deficiency is probably more liable to venous thrombosis, and perhaps embolism as well, than is the normal person. The thrombosis of active life does not, of course, crop up nearly so often as that of post-operative, post-traumatic and post-partum states, to say nothing of generalized circulatory failure, but is brought up here because physicians and laity alike are only too apt to deny the possibility of its occurrence.

COURSE OF LOWER-LEG VENOUS THROMBOSIS

In the recent paper to which allusion has just been made¹⁰ and in a paper presently to be published,¹¹ I call attention to the various courses that may be pursued by a venous thrombosis beginning in the lower leg or foot. I point out that the process may remain local without causing pulmonary embolism, that it may form a dangerous propagating thrombus that spreads up into the femoral vein and is the usual cause of the most serious sort of embolism, that it may extend upward in a more or less adherent form, partly filling the femoral and iliac veins, a rather prolonged disease with which a complicating thrombosis of the deep muscular veins of the thigh is likely to be associated, and which often ends fatally or that it may extend upward in a quiet form until, for reasons of which nothing is as yet known, it acquires an inflammatory element, to plug completely the femoral and iliac veins, causing swelling of the entire leg and the familiar picture of phlegmasia alba dolens. In this fourth course, the commonest, perhaps, in past experience, a non-suppurative infection appears to be the added feature, leading to perivascular involvement that affects the arterial wall as well as the various sorts of nerves surrounding the great vessels in the region of the groin and pelvis. As a result of this perivascular inflammation, there occurs not only some degree of local contraction of the companion artery but by what seems to be a reflex mechanism, a generalized constriction of the vessels of the entire limb. This condition has been called "thrombophlebitis" in contradistinction to the quiet disease or, if one likes, the quiet preliminary stage of this same process, dubbed by Ochsner and DeBaKey¹² "phlebotrombosis."

Various opinions have been expressed concerning the importance of a distinction between phlebotrombosis and thrombophlebitis. In a recent paper, Ochsner and DeBaKey¹³ make no attempt to trace the connection between them, but dwell very properly on the necessity of treating the two sorts dif-

*The review, by the way, shows that early postoperative walking is of advantage in more ways than one. Even if it does not do away with postoperative thrombosis and embolism, it appears to diminish its incidence rather than otherwise.

heparin for the most part intramuscularly. They find that in the "coumarinized" patient, the effect of a single intravenous injection of heparin is to sustain a prolonged clotting time for even as long as twenty-four hours. Thus heparin need not be given continuously, and intramuscular doses* can be substituted. Following an initial pulmonary embolism, they give heparin intravenously for a few hours. In the meantime, dicoumarol is started by mouth and, after the intravenous heparin has taken effect, intramuscular injection of the drug is begun. They indicate that two 5-cc. doses of heparin each day are sufficient. Three hundred milligrams of dicoumarol is given by mouth the first day, 200 mg. the second, and thereafter the dosage is governed by the prothrombin level. To use this system safely, prothrombin levels must be determined daily and the clotting time measured twice daily, clearly a matter requiring adequate and intelligent assistance, by no means foolproof. Their observations have been made experimentally and on a series of 15 patients without accident.

Barker, Allen and Waugh,³² from the Mayo Clinic, treated a series of 497 cases, all postoperative. Their principal groups included those who had already survived a pulmonary embolism and those who had had postoperative "thrombophlebitis." They used dicoumarol principally. They made no attempt to distinguish phlebothrombosis from thrombophlebitis. They do not state how long their patients were followed (to detect late embolism after withdrawal of the drug). They had 47 cases — 10 per cent — of more or less serious bleeding and 1 fatal hemorrhage. Nevertheless they believe that they reduced embolism far below expectation according to the system of statistics used, and conclude:

Adequate elevation of prothrombin time by means of administration of dicoumarol by mouth to postoperative patients is apparently effective in preventing postoperative thrombosis and pulmonary embolism. A plan of administration whereby 300 mg. are given on the first day, 200 mg. on the second day and 200 mg. on each subsequent day that the prothrombin time is less than thirty-five seconds (normal, eighteen to twenty-two seconds) has proved satisfactory. At present it is unwise to give dicoumarol unless the prothrombin time can be determined accurately each day. There is some risk of bleeding in postoperative cases when dicoumarol is given, but this risk is comparatively small. If hemorrhage occurs, it can be controlled by transfusion of freshly drawn blood.

In an editorial, DeBakey³³ expresses the opinion that at the present time the postoperative use of anticoagulants is too apt to cause hemorrhage and that proximal ligation of the thrombosed vein is to be preferred. He voices distrust of the type of

statistics employed by Barker and his associates. I believe, however, that it would not be at all surprising if the combined administration of heparin and dicoumarol should prove exceedingly helpful when all known safeguards are used, and especially if discrimination is exercised in the selection of cases. DeTakats³⁴ has put forward a test for heparin tolerance, that is, the reaction of the patient's coagulation time to a standard intravenous dose of heparin. He finds that some patients are resistant to heparin; that is, they are thrombophilic, especially in the early postoperative period, following cardiovascular accidents and in Buerger's disease. Others are heparin-sensitive. His observations on various methods of giving heparin should be studied, and he recommends frequent tests, by the capillary glass-tube method, of the coagulation time. He advocates the combined use of heparin and dicoumarol.

Surgical treatment. Section or ligation of veins as a means of therapy seems to have been advocated chiefly by Boston surgeons. The recent publication of Allen, Linton and Donaldson¹⁰ gives as fair a picture of indications and results as is at present available. The tendency is to use exploration of the superficial or common femoral vein for all early cases in which quiet thrombosis has been diagnosed, whether or not embolism has occurred, and to suck the thrombus out of the vein proximal to the groin whenever it is encountered. Allen and his associates, although constantly trying to improve their "diagnostic acumen," believe that in their attempt to cut off all possible sources of pulmonary embolism they will inevitably perform some unnecessary operations. I¹⁰ have employed similar methods but have attempted to distinguish the more chronic and recurrent forms of thrombosis marked by extension of the quiet process into the iliac veins. For such cases I have employed section of the common iliac vein, which I advocate, and in a paper now in publication I¹¹ debate the pros and cons of this higher operation and the indication for ligation of the lower vena cava, a procedure that surely has a limited though definite field of usefulness. In this connection, it is of considerable interest that Shackelford and Whitehill³⁵ report the successful section of the left common iliac vein in a soldier, twenty-eight years of age, who had suffered repeated pulmonary embolism during active military service. The patient had malaria, but the connection of the disease with venous thrombosis in the lower limb was probably not important.

For the technic of the various operative procedures to be employed one may consult the writings of Welch and Faxon,⁹ Welch, Faxon and McGahey,¹⁴ Allen, Linton and Donaldson,¹⁵ Fine and Sears,¹⁶ Homans³⁶ and others, but there are problems as yet unsolved. For example, if one is making an exploration of the vessel at the groin and finds a palpably thrombosed but presumably not fully ob-

*Very likely further satisfactory intramuscular or subcutaneous means of administering heparin will be developed. Recently a method has been reported from the Mayo Clinic by Bryson and Code,³⁰ who administered subcutaneously a suspension of powdered heparin in a beeswax-sesame oil mixture and found that a satisfactory and prolonged coagulation time could be secured in the experimental animal. The method has even been tried out on several patients. Bryson and Code allude to previous observations of Loewe, Rosenblatt and Lederer,³¹ who gave heparin in a mixture of gelatin, glacial acetic acid, glucose, a vasoconstrictor drug and water, reporting satisfactory observations on rabbits. It will be interesting to hear further from such attempts, which sound decidedly promising.

the electrocardiogram gave the first suggestive laboratory evidence of the correct diagnosis; in the rest it confirmed a clinical diagnosis. From the Mayo Clinic comes another report by Currens²¹ dealing with the importance of the electrocardiogram in the diagnosis of pulmonary embolism. This observer holds that the strain on the right ventricle seems to be the dominant factor in causing the electrocardiographic changes.

Phlebography. This diagnostic aid has proved, on the whole, disappointing. It has been advocated as a trustworthy means of making an early diagnosis (following the lead of dos Santos²² and of Bauer²³) by Welch, Faxon and McGahey,¹⁴ by Starr, Frank and Fine²⁴ and, more recently, by DeBakey, Schroeder and Ochsner.²⁵ On the other hand, Allen, Linton and Donaldson,¹⁵ reversing the opinion expressed earlier by the Massachusetts General Hospital group, find it rather untrustworthy, for, as they say, phlebograms are difficult to interpret and may be misleading. In this latter view, I join. The phlebogram, if positive, is sometimes astonishingly accurate and defines the thrombus and its extent in a way that no other diagnostic procedure can do, but in too many cases it leaves the diagnosis unproved, particularly in cases in which it is imperative that further pulmonary embolism should be prevented, and sometimes it suggests a positive diagnosis of thrombosis when no such process is present. In other words, the filling of the deep veins of the lower leg by a solution opaque to the x-ray is a somewhat uncertain procedure. I have found it most useful and reliable in giving information concerning a past or present thrombosis in the femoral vein, that is, in the deep vein above the knee. In the case of a rather chronic process, it may be very helpful to know whether to section the femoral vein proximal to the thrombus or whether one must go higher and expose the common iliac or the vena cava, but this is by no means making a diagnosis in the early or doubtful case; it is merely a refinement of a diagnosis already made.

TREATMENT

Heparin and dicoumarol. When one reads the publications of those accustomed to deal with deep venous thrombosis and pulmonary embolism by operative means, one is hardly made aware that such a treatment as the administration of heparin or dicoumarol exists. Yet when one reads Murray's²⁶ statement that, following an initial pulmonary infarction, not one of his 46 heparinized patients suffered a fatal pulmonary embolism, one must agree that there is virtue in this method. A recent report by Evans,²⁷ from the Lahey Clinic, on a short series of cases in which he depended mainly on dicoumarol (with which he sometimes combined heparin) presents certain advantages for this line of treatment, although it must be admitted that the death of 2

patients in 56* from hemorrhage is disconcerting, to say the least. So far as Boston is concerned, Evans appears to be a voice crying in the wilderness, but he receives support from other parts of the country. A recent editorial in the *Journal of the American Medical Association*²⁸ comments favorably regarding the prevention of venous thrombosis by the administration of dicoumarol to the experimental animal.

What troubles me in attempting to assay the value of the heparin-dicoumarol treatment is that in the reports I have so far studied, *postoperative* thrombosis has been, practically speaking, the only sort on which a trial has been made, thrombophlebitis has been lumped together with the quiet, dangerous type, — 13 out of Evans's 17 postoperative cases were of the inflammatory, obstructive sort, whereas only 4 represented phlebothrombosis — and, moreover, no parallel series of operative versus drug therapy in any large clinic is known to me to have been undertaken. Actually, the great field of thrombosis and embolism in those confined to bed by cardiac, pulmonary and other serious diseases has hardly been touched. These are fundamental omissions. It only appears, so far, that heparin is capable, if properly administered, of preventing the onset of thrombosis; that is, if given after operation, thrombosis and embolism are unlikely to occur. This, of course, is good, and if heparin were not so expensive and its administration were not so difficult and time-consuming a matter, heparinization, as a prophylactic, at least, could be freely recommended. So far as heparin alone is concerned, one cannot go much farther. Many surgeons believe that if given carefully, when pulmonary embolism has already taken place, it will halt embolism during the actual period of its administration but will not prevent a fatal recurrence following withdrawal of the drug.

Dicoumarol, in contrast with heparin, is cheap, is given by mouth and, by profoundly lowering the prothrombin level in the blood, prevents thrombosis. Thus it has certain advantages. But whereas heparin acts to prevent both clotting and adhesiveness of the thrombocyte (a basic part of thrombosis) only during its administration, and rapidly leaves the blood stream as soon as no more is introduced, dicoumarol continues to hold down the prothrombin level for many days after even moderate doses. Yet it does not delay coagulation. It may even cause serious or fatal bleeding while not prolonging the clotting time at all, and its dangerous effect can only be combated by the introduction of prothrombin through abundant transfusion of whole blood. For such reasons, Rhoads, Walker and Panzer²⁹ believe that dicoumarol and heparin should be looked on as complementary drugs and should be given together — dicoumarol by mouth and

*Actually only 46 cases of thrombosis or with a history of venous thrombosis were treated with dicoumarol and no deaths from hemorrhage occurred among them

heparin for the most part intramuscularly. They find that in the "coumarinized" patient, the effect of a single intravenous injection of heparin is to sustain a prolonged clotting time for even as long as twenty-four hours. Thus heparin need not be given continuously, and intramuscular doses* can be substituted. Following an initial pulmonary embolism, they give heparin intravenously for a few hours. In the meantime, dicoumarol is started by mouth and, after the intravenous heparin has taken effect, intramuscular injection of the drug is begun. They indicate that two 5-cc. doses of heparin each day are sufficient. Three hundred milligrams of dicoumarol is given by mouth the first day, 200 mg. the second, and thereafter the dosage is governed by the prothrombin level. To use this system safely, prothrombin levels must be determined daily and the clotting time measured twice daily, clearly a matter requiring adequate and intelligent assistance, by no means foolproof. Their observations have been made experimentally and on a series of 15 patients without accident.

Barker, Allen and Waugh,³² from the Mayo Clinic, treated a series of 497 cases, all postoperative. Their principal groups included those who had already survived a pulmonary embolism and those who had had postoperative "thrombophlebitis." They used dicoumarol principally. They made no attempt to distinguish phlebothrombosis from thrombophlebitis. They do not state how long their patients were followed (to detect late embolism after withdrawal of the drug). They had 47 cases — 10 per cent — of more or less serious bleeding and 1 fatal hemorrhage. Nevertheless they believe that they reduced embolism far below expectation according to the system of statistics used, and conclude:

Adequate elevation of prothrombin time by means of administration of dicoumarol by mouth to postoperative patients is apparently effective in preventing postoperative thrombosis and pulmonary embolism. A plan of administration whereby 300 mg. are given on the first day, 200 mg. on the second day and 200 mg. on each subsequent day that the prothrombin time is less than thirty-five seconds (normal, eighteen to twenty-two seconds) has proved satisfactory. At present it is unwise to give dicoumarol unless the prothrombin time can be determined accurately each day. There is some risk of bleeding in postoperative cases when dicoumarol is given, but this risk is comparatively small. If hemorrhage occurs, it can be controlled by transfusion of freshly drawn blood.

In an editorial, DeBaKey³³ expresses the opinion that at the present time the postoperative use of anticoagulants is too apt to cause hemorrhage and that proximal ligation of the thrombosed vein is to be preferred. He voices distrust of the type of

statistics employed by Barker and his associates. I believe, however, that it would not be at all surprising if the combined administration of heparin and dicoumarol should prove exceedingly helpful when all known safeguards are used, and especially if discrimination is exercised in the selection of cases. DeTakats³⁴ has put forward a test for heparin tolerance, that is, the reaction of the patient's coagulation time to a standard intravenous dose of heparin. *Very likely further satisfactory intramuscular or subcutaneous means of administering heparin will be developed. Recently a method has been reported from the Mayo Clinic by Bryson and Code,³⁷ who administered subcutaneously a suspension of powdered heparin in a beeswax-stearine oil mixture and found that a satisfactory and prolonged coagulation time could be secured in the experimental animal. The method has been tried out on several patients. Bryson and Code allude to previous observations of Loewer, Rosenblatt and Lederer,³⁸ who gave heparin in a mixture of gelatin, acetic acid, glucose, a vasoconstrictor drug and water, reporting satisfactory observations on rabbits. It will be interesting to hear further from such attempts, which sound decidedly promising.

structed femoral vein, is it better to suck out all removable thrombus and section the vein, or shall one leave the vein alone and, closing the wound, undertake a common iliac division or even ligation of the vena cava? This matter is urgent because one may fail to remove all thrombus by suction, and subsequently, further detachment of material from some part of the iliac veins may occur. Another problem is the question whether, in such a case as has just been postulated, heparinization or a combined administration of heparin and dicoumarol shall follow the operation. Still another uncertainty is whether bilateral femoral division shall be performed in all cases of serious pulmonary embolism even though only one limb clearly exhibits signs of thrombosis. Finally, in the case of a breathless patient whose pulmonary arteries are evidently full of emboli and whose lower limbs show no convincing signs of thrombosis, shall one undertake the risk of attempting a division of the vena cava, or shall one expose both femoral vessels and suck out the soft thrombus, or shall one abandon operative surgery altogether and attempt to cure the patient by the combined use of heparin and dicoumarol? Settlement of these matters is most urgent in the case of extremely ill medical patients, especially those suffering from cardiac disease, for which a wide-awake medical service in any large hospital is likely in these days to seek treatment. Embolism may already have occurred without any positive signs of thrombosis in the legs, or in the absence of any signs of embolism, the legs themselves may be suspected of harboring a deep thrombosis. In a two-month period (February and March, 1944) at the Peter Bent Brigham Hospital, twelve vein interruptions were performed on medical cases as compared with six surgical ones. Most were femoral sections, but two ligations of the vena cava were made. The higher operations are most decisive, but are they too dangerous? If a general anesthetic seems to carry too great a risk, division of the vena cava can perhaps be performed under a right-sided paravertebral procaine block. Doubtless, the patient's economic situation, the operator's skill and the familiarity of all concerned with the various methods of treatment will be found to be controlling factors in standardizing treatment.

Ligation of the vena cava has long been practiced sporadically by gynecologists and obstetricians. A recent account has been given by Collins, Jones and Nelson.³⁷ Of course, the thromboses beginning in the pelvis, and especially those of a septic sort following uterine infection, require section of the ovarian veins as well as of the vena cava itself and therefore call for a transperitoneal operation. It appears that such a procedure is somewhat different in its effect from division of the vena cava alone in the case of thrombosis beginning in the legs, and the results of the operations performed because of thrombosis complicating pelvic sepsis

should not be used as guides in interpreting the after-effect of extraperitoneal ligations of the vena cava for phlebothrombosis of the lower leg. Undoubtedly my experience with section or ligation of the common iliac vein indicates that the venous return from the lower limb following this operation is much more satisfactory than that following division of the femoral vein. The same is not quite true of division of the lower vena cava, for in that case shunting of the blood from one side of the pelvis to the other is not available. It is proper to say, however, that in the observation of the dozen or so cases of division of the vena cava of which I have knowledge (unpublished observations), the subsequent venous return from the legs has been remarkably satisfactory and no serious aftereffects have as yet been observed.

It will be noted that nothing has been said of the treatment of thrombophlebitis (phlegmasia alba dolens) by lumbar sympathetic procaine block. Actually no new information as the results of this valuable procedure has appeared within the last two years.

VENOUS THROMBOSIS ASSOCIATED WITH ARTERIAL OBSTRUCTION

The association of venous thrombosis with arterial obstruction of various sorts, particularly in the lower limbs, has received insufficient attention. It would be rather trite to observe that there is such a disease as thromboangiitis obliterans, a disease in which venous and arterial thromboses are intimately associated. It is not even known, for instance, whether the primary process lies in one sort of vessel or the other. One sees, however, occasional cases in which arterial stoppage is obviously primary, yet with which there is so much venous stasis as to suggest that venous has become associated with arterial obstruction. I have also encountered pulmonary embolism in combination with some rather chronic arterial deficiencies. In this connection, an unusual paper was published some years ago by Cornil, Mosinger and Audier.³⁸ After calling attention to the association of phlebitis with arteritis in Buerger's disease and pointing out that arterial symptoms are frequently present with thrombophlebitis, they undertake to explain how thrombosis may be communicated from large artery to companion vein or from companion vein to large artery. They believe that with perhaps 40 per cent of arterial closures there is an associated venous thrombosis. In explanation, they show that the media and adventitia of the veins contain capillary vessels, supposedly lymphatic, which they find present only in the adventitia of the arteries. An inflammatory reaction starting within the arterio-venous sheath may extend, therefore, in a lateral direction and even longitudinally, the subsequent lateral extension producing results at a distance from the original lesion. When an inflammation

reaches the vein from the artery, it may occupy both the adventitia and the media, a phenomenon that would explain the frequent thrombosis of large veins associated with arterial disease. But when an inflammatory process is communicated from vein to artery, it involves only the adventitia and so causes spasm of the arterial wall rather than thrombosis. All such reactions depend on the enclosure of large arteries and veins in a common sheath within which are included the anastomosing lymphatic vessels.

Several communications are available relating to the presence of venous thrombosis and even pulmonary embolism in obstructive arterial disease. Veal³⁹ finds it worth while, in thigh amputations for gangrene of arterial origin, to ligate the femoral vein before amputation is performed. He believes that by so doing he prevents considerable pulmonary embolism. Atlas⁴⁰ describes a rather complicated case of thrombosis and embolism following amputation in which he was obligated to divide the vena cava, and I (unpublished data) have noticed, in connection with an unexplained arterial embolism that had caused gangrene of the lower leg, an associated thrombosis of the femoral vein obviously secondary to the lodgment of the embolus. This was discovered in an exploration of the femoral vessels at the groin in a search for the cause of the gangrene. Resection of that part of the artery containing the embolus, and of the companion vein as well, was employed. Such observations as these offer an explanation of the obvious venous engorgement associated with some fairly acute and outspoken obstructions in the femoral artery and perhaps account for the heat that is present in the feet of some of these patients, a heat obviously not due to infection and rather difficult to explain solely on a basis of a sudden cutting down of the arterial stream. Possibly, venous thrombosis associated with a sudden arterial occlusion is a useful natural provision, raising the venous pressure in the periphery of the limb and so actually improving the nutrition of the peripheral parts. Occasionally, of course, the associated venous thrombosis is a quiet one, almost necessarily overshadowed by the arterial occlusion, and if only partly obstructive is of the type that causes pulmonary embolism.

Venous pressure and the arterial circulation. Although not strictly relevant to the subject of diseases of the veins, the reaction of local venous pressure in a limb on the arterial circulation is an important matter and has recently received a good deal of discussion. It will be recalled that for some years intermittent venous occlusion has been recommended as a means of establishing a collateral circulation, in connection with various sorts of arterial obstruction and deficiency. Linton, Morrison, Ulfelder, and Libby⁴¹ demonstrated to their own satisfaction in the experimental animal that occlusion of the principal vein of a limb induced increased

arterial pressure in that limb, and that there were relations between the point at which the occlusion was made, and the length of time it was maintained, with the degree to which arterial pressure was elevated. The whole matter is related to the circulatory balance, which has long been regarded as of fundamental importance when large arteries must be sacrificed. The observations of these writers were consistent with the practice of dividing the companion vein at the same level as the arterial section or higher. More recently, Friedland, Hunt and Wilkins⁴² have measured the arterial flow in the extremities of human beings with and without the venous congestion produced by inflating a blood-pressure cuff on the proximal part of the limb. They tested the flow by various methods and found that it was not increased in the limbs during the rise of venous pressure but on the contrary was usually decreased. This subject comes up acutely, of course, in these war times when a wounded limb is on the borderline of gangrene as a result of a serious arterial injury. Ligation of the companion vein, hitherto regarded as essential, may prove to be less important than intermittent depression of the level of the wounded limb, the idea being to secure some degree of venous engorgement without bringing on a harmful edema. "Intermittent venous occlusion" in treating various sorts of arterial deficiency in the lower limbs is still on trial.

THROMBOSIS IN VARIOUS VEINS OF THE BODY

Idiopathic recurrent thrombophlebitis. Bucy and Lesemann⁴³ report a remarkable case of recurrent thrombophlebitis in which the condition was exhibited over a period of fifteen years in various parts of the body. The disease had shown itself, previous to the most recent episode, in both legs and one arm. Finally it involved some of the cerebral cortical veins and the retinal veins of the right eye. Associated with this attack was an acute subdural hemorrhage, requiring evacuation of the hematoma. The patient recovered. The literature is summarized.

Mesenteric thrombosis treated with heparin. Luke⁴⁴ reports a case of venous mesenteric thrombosis in a soldier of forty-two. The history and physical examination were typical. Exploratory operation disclosed thrombosis in the mesenteric veins serving about 135 cm. of small bowel. The intestine appeared barely viable. The patient recovered under heparinization.

Septic thrombosis of cavernous sinus. Schall⁴⁵ reports 3 patients suffering from cavernous sinus thrombosis of the anterior type, with staphylococcal bacteremia, successfully treated by sulfathiazole and heparin. Sulfathiazole was given in sufficient dosage to maintain a blood level of 5 mg. per 100 cc. and was continued for a long period after the administration of heparin was discontinued. Schall discusses the theoretical value of this combination, as suggested by Lyons,⁴⁶ and the possible use of

sulfonamides other than sulfathiazole. Apparently the principle of combining heparin with a sulfonamide is a sound one.

VARICOSE VEINS

It is to be observed that the tendency evident in previous progress notes on varicose veins has continued. Papers are appearing describing technics for sclerosing injection, but on the whole the study of etiologic factors and of the interrelation of varicose veins and venous pressures has been more in evidence. In 1942, favorable comment was made on Adams's⁴⁷ communication discussing pressure in varicose veins as compared with normal veins of the lower extremities. Adams showed that, in the standing position, pressure in both sorts of vessels was equally due to gravity alone, unless coughing or straining occurred. Then, pressure in the valveless varicose veins rose even to arterial heights, whereas in the well-valved femoral system this extra rise failed to occur. One corollary of his work was to belittle the value of elaborate tests for incompetent communicating veins, "blowouts" and so on, since adequate high ligation prevents the rise of pressure in varicose veins below the interruption, due to straining, and pressure in such veins, which are connected only with the valved femoral system, continues to represent the effect of gravity and of gravity alone, whether or not communicating veins are also interrupted. Another significant communication was that of Veal and Hussey,⁴⁸ who found elevated pressures in the popliteal veins of pregnant women, showing how functional incompetence of valves explains the well-known causal relation between pregnancy and varicosity. In this connection, it will be noticed that Adams advised the addition of straining to the Trendelenburg test, which ordinarily records the effect of gravity only, for by that means the actual clinical competence of the varicose veins to forward blood and resist high back pressure can be determined.

Etiology. Eger and Casper⁴⁹ believe that since there are no valves in the vena cava and common iliac veins, it is the role of such valves as are present in the external iliac veins to support, proximal to the legs, the long column of venous blood. Actually, these valves are inconstant, and their absence imposes a greater than natural burden on those in the femoral system below. If valves in the common femoral vein are also wanting, the saphenous, as well, is directly exposed to high back pressures. In 7.9 per cent of their cadavers, Eger and Casper found a bilateral lack of valves above the orifice of the great saphenous, and in 35.8 per cent absence of valves on one side or the other. Only one valve is likely to be present in any case above the great saphenous. There was no valve on the right in 10.4 per cent and on the left in 18.5 per cent. They conclude that if lack of valves is the etiologic factor, varicosities should develop unilaterally in 29 per

cent and bilaterally in 8 per cent of all persons. The left leg should show varicosity twice as often as the right. Another possible etiologic factor is an obstructive anomaly at the mouth of the left common iliac vein, to which attention is called by Krumbhaar and Ehrlich.⁵⁰ This they found present in 30 per cent of 280 autopsies.

Pathologic physiology of varicosity. Chapman and Asmussen⁵¹ bring up a subject as to which I have always been curious. I have expected to meet some time a patient suffering from extensive varicosities who experienced faintness on standing up, owing to the rapid downpouring of blood into capacious valveless veins. Actually I have never encountered this phenomenon, but Chapman and Asmussen go at the problem in a more scientific way. Starting with the fact that even normal persons are likely to accumulate in their lower limbs some 500 cc. of blood when standing still (over and above the amount which is present in the horizontal position), and recognizing the diminished output of the heart that has been observed to result, they have investigated some of the logical effects of the even greater downpour of blood into greatly dilated varicose veins. They find that, as compared with normal persons, those having large varices suffer a fall of cardiac output four times as great, a greater lowering of systolic blood pressure and a more marked increase in the pulse rate. After high interruption of the varicose veins, these tendencies are for the most part corrected. Patients suffering from shortness of breath, dizzy spells and faintness are greatly relieved. It is to be noted, however, that not all patients in whom the cardiac output is lowered excessively by the assumption of the upright position make any actual complaints. It appears therefore that only those on the borderline of cardiac incompetence are consciously suffering from the pooling of their blood in varicose veins. The authors note also an increase in blood volume in the varicose patient.

Venous pressure in the presence of varices has also been studied by Mayerson, Long and Giles.⁵² Aware of the investigations of both Adams and the authors just quoted, they reason that since the vascular bed, in the presence of varicosity, is greatly enlarged, there must be a concomitant increase in blood volume similar to that of hyperthyroidism, cardiac disease and arteriovenous fistula. Thus, when the varicose patient assumes the horizontal position, his vessels contain more blood than he needs and consequently venous pressure rises. They show this high pressure to be present in the arms as well as the legs in their recumbent patients.

Such considerations as these bring up the rather interesting point whether high ligation without actual obliteration of varicose veins does for the borderline case all that might be accomplished in the way of reducing the capacity of the vascular bed. Partly with this point in mind, I carry out a low-

CASE 30281

PRESENTATION OF CASE

A seventy-five-year-old housewife entered the hospital because of abdominal pain.

The patient had been in apparent good health until three or four months before admission, when she had the "grippe" for several days. Following this she felt poorly. During the week before entry she had extreme constipation, relieved by high colonic irrigations, and accompanied by considerable anorexia and frequent vomiting. On the evening of admission she suddenly had severe epigastric pain, went into collapse and sweated profusely. She was seen half an hour later. She had severe epigastric pain, which did not radiate, associated with considerable retching and vomiting. The vomitus consisted of clear frothy material. The neck veins were distended, but the venous pressure as measured by raising the arm above the level of the heart was not elevated. The pulse was rapid and weak. The blood pressure, which on one occasion had been recorded as 180 systolic, was found to be 130 systolic, 70 diastolic. After about one hour the pain subsided and she was sent to the hospital.

The patient had had Paget's disease of the bone for many years, without any skull enlargement. For several years she had had one good meal daily but the diet had not been well balanced. Five years before entry she apparently had a similar episode of epigastric pain, which was treated by her physician.

Physical examination on admission showed a poorly nourished, pale, dehydrated woman. The lungs were clear. The heart was enlarged to the left and the sounds were forceful and regular. There was tenderness in the right upper quadrant and in the epigastrium. The liver edge was palpable.

The blood pressure was 110 systolic, 70 diastolic. The temperature was 97.6°F., the pulse 110, and the respirations 25.

Examination of the blood showed a white-cell count of 21,800, with 87 per cent neutrophils. The red-cell count was 3,430,000, with 9.5 gm. of hemoglobin. The urine had a specific gravity of 1.010 and gave a ++ test for albumin; the sediment contained 6 red cells and 12 white cells per high-power field and occasional coarse granular casts.

Plain films of the abdomen showed all the bones to be markedly decalcified, with coarse trabeculations. Along the brim of the left side of the pelvis there was cortical thickening suggestive of Paget's disease. The kidneys and psoas contours appeared normal. There were no dilated loops of intestine.

X-ray films of the chest showed the lung fields to be radiant. The chest was deep. The pulmonary markings were somewhat prominent. The diaphragm was somewhat depressed. The heart was enlarged in all diameters. The aorta was moderately tortuous.

The evening of admission the patient had a second attack of pain. This time the pain was in the right upper quadrant and radiated to the right shoulder. She became cold and clammy, with a rapid and weak pulse. The blood pressure remained unchanged. The pain was relieved by 1/6 gr. of

*On leave of absence

morphine. During the night she had two more similar attacks. In the morning she continued to have tenderness in the epigastrium. The neck in the thyroid region seemed swollen. She spoke as if she had a "hot potato in her mouth," and she stated that her throat felt sore. An ice collar applied to the neck and hot gargles seemed to bring about some regression of symptoms.

Twenty-four hours and thirty-six hours after admission the patient had two other attacks of pain in the right upper quadrant radiating to the shoulder. Examination was essentially as before, with the addition of some stridor, which was relieved when she was propped. The pain was relieved by morphine. She was given intravenous fluids and 100 cc. of blood. There was some difficulty in getting into the veins because they were collapsed. On the second hospital day, about forty-eight hours after the onset of her illness, she seemed better and more cheerful but suddenly went into collapse and died.

DIFFERENTIAL DIAGNOSIS

DR. ARTHUR W. ALLEN: Let us look at the x-ray films.

DR. GEORGE W. HOLMES: The bones show the characteristic decalcification found in aged people. There is nothing in these films to suggest Paget's disease, and that diagnosis must have been made on the basis of other films. There is marked increase in the anteroposterior diameter of the chest, which one often sees in cases of emphysema, and in the other view of the chest the lungs are moderately bright and not inconsistent with this finding. The impression one gets from reading the report is different from that gained from these films. The heart is enlarged, but not strikingly so. There is a good deal of calcification in the bronchial tree and along the line you see here, which is rather confusing. The supracardiac shadow is wide. It does not give the impression of any great degree of tortuosity. There is a shadow above the aorta that could be the root of the innominate artery. Dilatation of the root of the innominate does occur when there are lesions of the aorta itself. In this lateral view the outline of the aorta is not sufficiently clear for me to decide whether it is abnormal. I am surprised that it does not show better. With a normal aorta in a patient of this age, one would expect to see its outline better than one does in this film.

DR. ALLEN: There are a number of things about this record that I question, and it would be helpful to have considerable additional information.

Obviously this case must have been considered as a questionable acute abdominal emergency, although there is no note to that effect. The first thing that interests me is that until the patient had what was diagnosed as "grippe" she had been well, and after that she had not been well for a period of three or four months. I do not know what kind of illness this was. The term "grippe" covers a mul-

titude of disorders. It does not say whether she had gastrointestinal symptoms at that time, although people occasionally classify some types of gastroenteritis under the general heading of grippe. The record does not state whether the patient had any fever through the months before her acute illness. It is possible that she had a low-grade fever with her prolonged malaise.

The week prior to entry she had extreme constipation, which is not unusual in a woman of seventy-five who is as thin as the x-ray films show this patient was. These elderly people frequently have obstipation. We are told that the constipation was relieved by high colonic irrigations, so it appears that this episode five days prior to entry was not due to intestinal obstruction. The severe sudden pain probably was not associated with the colonic irrigation. I assume that it was not because I think that it would have been so stated if there had been any relation. Of course, sudden severe abdominal pain from perforation of a diverticulum or from perforation of a weak spot in the bowel sometimes does follow irrigation of the colon. The pain was sudden and severe and in the epigastrium. She went into collapse and sweated profusely, and her physician apparently saw her within half an hour. He obviously was impressed with the fact that she was quite ill, because as soon as he could arrange it, she was brought to the hospital. They state that the epigastric pain did not radiate, and that may have been true. It is possible that she was in considerable shock either from pain or from the trouble that had brought on the pain; if so, she might not have been able to differentiate too well whether the pain started in the epigastrium or to where it radiated. She did have retching and vomiting, however, which probably arose not from the pain or from the morphine but from the lesion itself.

The statements that the neck veins were dilated and, later, that there was swelling in the thyroid region bother me a great deal and I have difficulty tying those together with the rest of the picture. They may be important in the differential diagnosis, but I am unable to link them up with the lesion that I believe this woman had.

She had a drop in blood pressure, which indicates shock, and farther on we see that the red-cell count was 3,500,000, with 9.5 gm. of hemoglobin, indicating the possibility of blood loss. Later in the record we see that she had been having one meal a day, and it is stated definitely that the diet was deficient; so possibly, and quite probably, the red-cell count and hemoglobin were about as reported, even before the episode of acute illness came on. One of the important pieces of data that we are given is the leukocytosis of 21,800, with a differential count of 87 per cent neutrophils. It is unusual to get that amount of leukocytosis with an elevation of the neutrophils on the basis of anything else except inflammation or gangrene. To be sure, it does occur with some of the other conditions,

woman had had no injury, and we have no reason to suppose that that was what she had. Bleeding into the peritoneal cavity from a ruptured aneurysm or ectopic pregnancy will cause some elevation in the leukocytes, but not to this degree. Mesenteric thrombosis produces extreme leukocytosis, but Dr. Wyman Richardson has recently told us that an elevated leukocyte count in mesenteric thrombosis is not often associated with an increase in the ratio of the polymorphonuclear cells. None of the surgical service were aware of this, and the one patient on whom we have had an opportunity to test this point since we received the information was apparently an exception to the rule because she had the same elevation of neutrophils that the patient described here had.

Could the "grippe" have actually been an endocarditis? Did she go on for a period of three or four months and then develop thrombi that were given off and finally went into the arterial circulation of the mesentery? This would explain the entire picture in spite of the fact that we have no evidence of a distended bowel in the flat film of the abdomen. One early x-ray examination may be of no particular value. We have little in the record telling us about the final examination so far as the abdomen is concerned. The suddenness of the onset, the severity of the pain, the associated vomiting, which was nonfecal, and the high leukocyte count, — in mesenteric thrombosis it may be much higher than it was in this patient, — all occurring three months after some kind of illness, may form the basis on which to reconstruct this case. The difficulty is that she lived a little long for mesenteric thrombosis of the usual progressive type. Also, it states that on the second hospital day, forty-eight hours after the onset of the illness, she seemed more cheerful but suddenly collapsed and died, which suggests further progression, either perforation of a hollow viscus or something that had to do with the cardiovascular system.

I shall leave the discussion at this point and say that this patient had arteriosclerotic disease and Paget's disease, with all due respect to Dr. Holmes. Also, there was an acute affair, which, I believe, is more likely to have been mesenteric thrombosis than anything else. Of course one must consider the possibility of other acute diseases that involve the upper abdomen, such as perforated ulcer, which would be all right for the length of time she lived, or acute cholecystitis. Patients do not die suddenly from acute cholecystitis; but, when they do, it is usually within a few minutes after the gall bladder ruptures.

DR. CHESTER M. JONES: This patient's symptoms were interesting in that they were referable to the throat and that she had swelling there. Can you tie those facts in with the symptoms of the abdomen? It seems to me that she died of symptoms referable to the neck.

DR. ALLEN: They say that there was definite improvement following the application of an ice collar. I cannot tie the neck symptoms with those of the abdomen. Have you any idea?

DR. JONES: No, except that she had swollen neck veins, which suggest something vascular.

DR. J. H. MEANS: The neck bothered me a good deal. I could not laugh it off, nor could I hook it up with the abdominal diagnosis unless it was on a vascular basis. The story of sudden onset, of doing better and suddenly dropping dead makes one wonder if she had a cerebral embolus. Dr. Allen has suggested the possibility of endocarditis, which is a good one. If she had had one embolus going to the mesentery, she could also have had one going to the cerebrum and causing sudden death. The findings in the neck associated with sudden death remind me of a case that I discussed in which there was sudden demise during a thyroid operation, which turned out to have been due to a cerebral embolus. It seems to me that it is easy to hook up the various phenomena present here on the basis of some kind of cardiovascular or vascular lesion, but precisely what, is difficult to say. Knowing the department's diabolical ingenuity in framing us, and since the first case discussed today was a dissecting aneurysm, I wonder if they might have lined up two dissecting aneurysms for us. It is conceivable, although I am throwing the suggestion out very cautiously.

DR. JACOB LERMAN: When I first saw the patient it was quite obvious that she was in shock. She was exquisitely tender over the epigastrium and had recurring attacks of pain, which finally shifted to the right side. My attention focused on the gall bladder. Consequently I had a surgeon see her, who agreed it was probably an episode of acute cholecystitis. He did not advise surgery, however, because her condition was so poor. She had an anemia, which was greater than that indicated by the red-cell count of 3,500,000, because she was dehydrated when the count was taken. I also was disturbed by the distended veins and by the swelling of the neck, which was definite and did not recede until an ice collar was applied. I raised the question of acute thyroiditis. It was difficult to explain the swelling of the neck and the stridor. The latter improved on elevation of the head. We thought that these symptoms were secondary to throat infection, and let it go at that.

CLINICAL DIAGNOSES

Acute cholecystitis, with perforation?
Paget's disease.

DR. ALLEN'S DIAGNOSES

Mesenteric thrombosis (secondary to subacute bacterial endocarditis).
Arteriosclerotic disease.
Paget's disease.

ANATOMICAL DIAGNOSIS

Aortic aneurysm (? syphilitic), with rupture into mediastinum and right pleural cavity and hemorrhage into soft tissues of neck and walls of esophagus and stomach.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy on this patient showed an extremely interesting lesion. When we opened the abdomen, the first thing that struck us was the marked hemorrhagic appearance of the surface of the stomach. There was no free blood in the abdominal cavity; the blood appeared to be in the wall of the stomach, extending down from the cardia to about the beginning of the antrum. When the chest plate was removed, about a liter of fresh blood was found in the right pleural cavity, and this hemothorax was undoubtedly the cause of the sudden exitus. The source of this hemorrhage was a perforation of an aneurysm of the descending thoracic aorta. The entire mediastinum was filled with blood clot, some obviously very recent from the terminal rupture and some definitely older. It was this older blood that had apparently been oozing from a subacute perforation of the aneurysm and had extended up into the neck. We found a huge amount of blood surrounding all the vessels of the neck and compressing the esophagus. The blood had permeated through the outer coat of the esophagus and had extended as a hematoma between the muscle layers and the adventitia. When it reached the stomach, a large part of the blood entered the muscle layers of the stomach and appeared as a submucosal hematoma, which bulged into the lumen. The appearance was not unlike that seen in intramural tumors of the stomach, such as leiomyomas and neurofibromas. The aneurysm was saccular, measured 6 cm. in diameter and was probably syphilitic in origin. There was no dissection of the aorta.

In retrospect, the peculiar appearance of the aorta in the x-ray film that Dr. Holmes mentioned was of some significance.

DR. HOLMES: The x-ray appearance may be explained on the basis of the pathology demonstrated. The enlarged root of the aorta and the absence of the shadow of the descending aorta in the lateral view were in all probability due to the blood surrounding these vessels.

CASE 30282

PRESENTATION OF CASE

A twenty-five-year-old woman was admitted to the hospital because of bleeding from the nose and the gums.

The patient had apparently been well until the age of seventeen, when she developed recurrent attacks of sneezing and shortness of breath over a

period of one year. She experienced considerable fatigue and lost about 30 pounds in weight. She was admitted to a community hospital, where diagnoses of bronchial asthma, chronic sinusitis and bronchitis were made, and she was treated with ephedrine and potassium iodide. Many skin tests were positive and she was advised to regulate her habits accordingly. She was discharged but re-entered that hospital five months later because of nausea and vomiting of two weeks' duration. The blood pressure was 150 systolic, 105 diastolic. The white-cell count ranged between 10,000 and 20,000, with an eosinophilia of 6 to 30 per cent. While in the hospital she developed anemia. The urine showed albumin, red cells, white cells and hyaline and granular casts. One serum protein determination was reported as 9.1 gm. per 100 cc. A diagnosis of periarteritis nodosa was entertained, but a muscle biopsy was negative. The symptoms apparently cleared up; she was discharged after two months in the hospital and remained symptom free for about a year. At the end of that period, following an upper respiratory infection, she had recurrence of the asthma and re-entered the same hospital. Examination showed expiratory and inspiratory wheezes and groans, but no rales or dullness. The blood pressure was 160 systolic, 125 diastolic. The urine concentrated as high as 1.032 and showed a variable amount of albumin. The sediment almost constantly revealed 1 to 2 red cells, 2 white cells and 5 to 20 coarsely granular and hyaline casts per high-power field. The total urine albumin output varied from 2.6 to 18 gm. Phenolsulfonephthalein excretion tests were all in the neighborhood of 25 per cent of the dye in two hours. Both kidneys showed equally poor function, but cultures were negative. The blood nonprotein nitrogen varied from 49 to 26 mg. per 100 cc., and the total protein was 7 gm., with an albumin of 3 to 4.7 gm. and a globulin of 2.7 to 3.4 gm. The blood calcium was 12 mg. per 100 cc., and the blood phosphatase 4.4 mg. The asthma was rapidly brought under control. She was asymptomatic, but displayed little if any improvement in the kidney function and was finally discharged on the fifty-seventh hospital day. Following discharge she felt well until one and a half months before admission to this hospital, when she contracted an upper respiratory infection. Her nose started to bleed; at first the bleeding was spotty, but then it gradually increased. The bleeding occurred without any apparent exciting cause every two or three days and lasted for two or three hours. One month before entry bleeding from the gums was noted which was most marked from the region of the molars and alternated from one side of the mouth to the other. This continued for five or six hours at a time and was occasionally temporarily alleviated by the application of Dermital lotion and alum. The bleeding was more apt to occur at night, when she would wake up with a

mouthful of blood. During this period she noticed an itching sensation in the eyes, black and blue spots on the legs and, for two weeks before entry, swelling of the ankles, which disappeared with bed rest. She missed one menstrual period at the onset of this illness, and the second one, which started eight days before entry, was associated with much pain and many large clots, neither of which was normal. She had had some morning nausea without vomiting, but denied any possibility of pregnancy. Her physician had given her calcium gluconate without any effect.

During this six-year period she had had no fever except that associated with upper respiratory infections; she had also had no chills, joint pains, dysuria, hematuria, pyuria, incontinence or increased frequency. She had had measles, diphtheria, bronchitis and influenza as a child. Following diphtheria, at the age of fourteen, she had "kidney trouble," which kept her in bed for many months.

Physical examination showed a well-developed, moderately undernourished pale woman in no distress. A small amount of blood oozed from the nose. Some coagulated blood was present on the gums. A few squeaks were heard over the lung fields. The left border of cardiac dullness was 11 cm. to the left of the midline in the fifth space. The first sound was loud, and there was a grating early apical systolic murmur. The abdomen was negative. Numerous black and blue areas were present on both thighs. No skin nodules were palpable.

The blood pressure was 172 systolic, 98 diastolic. The temperature was 99°F., the pulse 112, and the respirations 22.

Examination of the blood showed a red-cell count of 1,420,000, with 50 per cent hemoglobin. The white-cell count was 6300, with 58 per cent neutrophils, 17 per cent lymphocytes, 6 per cent monocytes and 12 per cent eosinophils. During her entire stay, except as noted, the urine had a reaction of pH 6.0 and a specific gravity of 1.010. It showed a +++ test for albumin, and the sediment contained occasional white and red cells. A blood Hinton test was negative. The blood nonprotein nitrogen was 129 mg. per 100 cc., and the protein 6 gm. The prothrombin time was 21 seconds (normal, 18 seconds).

She was given blood transfusions. Various measures to control the bleeding were at first unsuccessful. She was placed on a high-vitamin and high-calorie diet. On the fourth hospital day the blood chloride was 117 milliequiv. per liter, and the sodium 146.8 milliequiv. The blood calcium was 9 mg., and the phosphorus 3.1 mg. per 100 cc.; the carbon dioxide combining power was 9.9 millimol. per liter. An x-ray examination of the chest showed rather diminished linear shadows behind the heart and the left hilus. The heart size was within normal limits. The aorta was more tortuous than usual.

On the seventh hospital day a gallop rhythm was heard. In addition, one or two observers heard mid-diastolic rumble. An electrocardiogram showed a normal rhythm of 90. The PR interval 0.20 second, and T_1 , T_2 and T_3 were upright. QR demonstrated slight tendency to low voltage. The axis was normal. The patient was placed on a daily regime of 3 gr. of digitalis, a fluid intake of 1700 to 2500 cc., 0.8 to 1 gm. of protein per kilogram of body weight, 7 to 10 gm. of sodium chloride, and 3 to 5 gm. of sodium bicarbonate.

On the thirteenth hospital day intermittent bleeding from the gums was noted, which was temporarily controlled by adrenalin packs, fibrin foam and raw beef and she was transfused with blood. The urinary output was 1000 cc. on an intake of 200 cc. The pH of urine was 6.5, and it gave a ++++ test for albumin. A blood nonprotein nitrogen was reported as 35 mg. per 100 cc. the chloride 107.1 milliequiv. per liter, and the carbon dioxide combining power 15.7 millimol. per liter. The sodium was 141.8 milliequiv. per liter, and the calcium 8.8 mg. per 100 cc. On the fifteenth hospital day the patient had considerable gastric discomfort, which was relieved after digitalis was stopped. In the course of the next few days she experienced headaches, dizziness, and pain and light flashes in the eyes. Fundal examination showed spasticity and narrowing of the arteriole without any exudate. A blood nonprotein nitrogen five days after the preceding determination was 34 mg. per 100 cc., and the carbon dioxide combining power 23 milliequiv. per liter. These two low nonprotein nitrogen determinations occasioned much confusion and mystification and premature rejoicing at the wonders of modern therapy until a repeat nonprotein nitrogen, six days later, was found to be 129 mg. per 100 cc. Because of the persistence of the intermittent bleeding from the gums which was sometimes fairly profuse, various dental measures, such as extraction of certain of the teeth and correction of faulty occlusion, were contemplated but deemed inadvisable. On the thirtieth hospital day, the nonprotein nitrogen was 164 mg. per 100 cc., the chloride 96 milliequiv. per liter and the carbon dioxide combining power 16 millimol. per liter. A blood urea nitrogen was 142 mg. per 100 cc. Two urea-clearance tests were 41 and 55 per cent normal. A phenolsulfonephthalein test showed no excretion in two hours. The urinary output was between 250 and 750 cc. daily on an intake of 1500 to 2000 cc. The pH of urine was 7.1 to 7.5, but the urinalysis was the same as before.

On the forty-second hospital day she developed anorexia, nausea, vomiting, increasing headache and dizziness, weakness, and bleeding from the gums and nose. She started to wheeze, ankle edema appeared, and there were transient episodes of numbness of the legs. A precordial friction rub was heard. The abdomen became distended. The urinary out-

It was below 250 cc. on an intake of 1500 cc. The nonprotein nitrogen was 186 mg. per 100 cc., the chloride 96 milliequiv. per liter, and the red-cell count 1,660,000. The nonprotein nitrogen gradually rose to 250 mg. per 100 cc., the chloride fell to 83 milliequiv. per liter, the blood protein remained over 6 gm. per 100 cc., and the calcium was 9.6 mg.

On the fifty-fourth hospital day the patient had a scattered papulopurpuric eruption on the face and trunk and considerable itching. Nausea and vomiting of dark-brown material continued, and she developed diarrhea; the precordial friction rub became extremely loud. She died on the fifty-ninth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. AUSTIN BRUES: This seems clearly to be a case of progressive renal failure terminating in uremia, with classic signs and symptoms. The somewhat temperamental nonprotein nitrogen level seems unnecessary for making a diagnosis of terminal uremia in view of a number of other observations, namely, hypertension, hemorrhagic diathesis, friction rub, anorexia, vomiting and diarrhea. We may therefore check off those findings in the case that are characteristic of renal failure and proceed to consider its etiology.

The question to be answered is, Was this a primary or localized disease of the kidney, or was it part of a more generalized disease, as was suggested in the hospital to which the patient was admitted some years ago?

On reading over the case the course of the disease appears to be that of a chronic glomerulonephritis following acute glomerulonephritis, with an acute exacerbation in the interval that has been described in detail. The first suggestion in the history that the patient had kidney disease occurs when she was said to have been confined to bed following diphtheria. It is worth pointing out that the type of acute kidney disease that progresses to chronic nephritis is rare following diphtheria and is frequent following streptococcal infection. We must consider that she possibly had a streptococcal infection along with the diphtheria or that in reality she had a streptococcal infection, if we are to take this seriously as part of the history. This was followed by a course which, so far as we are able to tell from the history, was characterized at times by a moderately elevated blood pressure, with a high diastolic pressure. Later, there was evidence of cardiac hypertrophy, clinically but not by x-ray examination, and evidence of change in the aorta beyond what is normal for her age.

The urinary findings showed albuminuria and red and white cells and casts in the sediment, the cells having been at all times apparently moderate in number. She showed a progressive anemia toward the end of her course. There appears to be a

plethora of laboratory findings, some of which are difficult to interpret. In particular, I should say that the terminal observation that the urea clearance was half of normal, whereas the patient failed to excrete phenol red during the course of the two hours, appears paradoxical. It seems clear that the patient had acidosis at her final admission, and the therapy for this acidosis was fairly successful. It also appears that some cardiac failure was present terminally, although the x-ray studies failed to show enlargement.

Regarding the probable anatomic findings, the presence of considerable albuminuria in the last stage of this condition suggests that the patient had not reached the stage of the very contracted kidneys of an extreme terminal, chronic glomerulonephritis.

With regard to the differential diagnosis of disease localized in the kidney, there seems to be little in this case to suggest another diagnosis. The absence of fever and chills and the extremely long course are against focal embolic nephritis from endocarditis, although cardiac murmurs were noted and they may have changed in the course of observation. There is no good evidence for pyelonephritis, and at one time a culture of the urine was made and found to be negative. Polycystic kidneys would hardly occur without a palpable mass on at least one side. I think that similarly obvious considerations are against renal tuberculosis and amyloidosis.

Regarding general diseases in which the renal phenomena may be prominent, although the patient had eosinophilia, anemia and a bleeding tendency, there is no special reason to assume the presence of leukemia, Hodgkin's disease or some other tumor that happened to involve both kidneys and the bone marrow.

I should like to consider why periarteritis nodosa was entertained as a possible diagnosis on the previous admission. Presumably this was because, in addition to the nephritis and hypertension, the patient had a high total protein and eosinophilia. Some consideration might also have been given to the pulmonary symptoms, suggesting that she had arterial disease involving the lung. There is, however, no evidence of a positive sort for this diagnosis, attractive as the thought might have been that such a diagnosis could be made during life. The fact that the patient apparently recovered during the interval between the previous admission and the present one is not necessarily against the diagnosis of periarteritis nodosa, because periarteritis nodosa does undergo remissions. Is there any possibility that the patient had periarteritis nodosa on the basis of sensitivity to sulfonamide drugs? All it is possible to say is that we have no evidence that the patient was subjected to sulfonamide therapy, although she had had a great many infections, particularly upper respiratory infections. It is entirely possible that such therapy may have

been given from time to time and forgotten. On the other hand the previous trouble occurred several years previously, possibly before sulfonamides were in common use. I therefore think that the diagnosis of periarteritis nodosa or other generalized vascular disease ought to be considered improbable, and that it is reasonable to make a diagnosis of chronic glomerulonephritis. If there is a radiologist here, I should like to have him comment on the diminished linear shadows in the chest.

DR. JOSEPH B. AUB: Is the lateral spine normal? Are the vertebrae normal?

DR. BENJAMIN CASTLEMAN: There is no radiologist here.

DR. WYMAN RICHARDSON: This patient was on the service for almost two months when I was visiting. We reached the same conclusion that Dr. Brues has, namely, that she had chronic glomerulonephritis. We simply toyed with the idea of periarteritis nodosa. She had an enlarged heart, and I do not know why it does not show by x-ray. She had a definite gallop rhythm, and we had the usual futile discussion concerning mid-diastolic murmurs. I was very much on the fence in this matter of murmurs, and I am quite ashamed of my note in the record. The thing that troubled the girl the most was the bleeding, and it also troubled me a great deal to explain it, although it is frequent with renal failure. It is suggested that the bleeding is due to toxic damage, whatever that may mean.

DR. BRUES: I see no mention of platelets.

DR. RICHARDSON: They were numerous.

I found it difficult not to take a completely defeatist attitude in regard to therapy and decided to send the girl home when the bleeding seemed to stop somewhat. The service felt that we ought to try to correct the chemical situation, which I think was the proper attitude to take. In spite of the fact that the acidosis was considerably improved, I could not see that the patient herself was any better. She went downhill from that point on.

DR. ALLAN M. BUTLER: I was asked to see the patient to render advice whether the bleeding was due to vitamin C deficiency. It was my opinion that a plasma ascorbic acid determination was not worth doing because it would give relatively little information in appraising vitamin C deficiency. For even if the plasma vitamin C were zero, it would not mean that the bleeding was due to a vitamin C deficiency. If, however, the white-cell and platelet content of ascorbic acid were reduced it would mean that the patient was suffering a deficiency severe enough to cause this hemorrhagic tendency. At that time, however, the laboratory was too busy with war work to determine the vitamin C content of the white cells and platelets. I suggested a therapeutic trial of vitamin C. Since the diet did not suggest deficiency, I thought that the bleeding was associated with the hypertension and anemia. I recommended transfusing the patient before re-

sorting to digitalization, and before seeing if sodium sulfate would affect the hypertension. It also seemed to me that an appraisal ought to be made of the renal function before any consideration was given to the desirability of doing a sympathectomy. As intravenous pyelograms had been taken at the other hospital, I suggested that it would be wise to get hold of them to see if any information could be obtained about possible anatomical anomalies that might be behind the renal disease.

The odd nonprotein nitrogen values are a good example of doing quantitative chemistry with technicians who are not expert chemists. The reason these two falsely low determinations were obtained is that the technician who did them carelessly added too much acid so that the final reaction was not alkaline enough and the color did not develop. It is the kind of error that crops in if technicians are not properly trained in the methods of quantitative chemistry.

The final thing is that the lack of blood pressures in the history as recorded here makes it hard to decide what went on in this patient. One wonders how much of the primary difficulty was cardiac failure and how much was due to renal failure.

DR. CASTLEMAN: Two days before she died the blood pressure was 115 systolic, 70 diastolic; the day before she died it was 130 systolic, 75 diastolic.

DR. BUTLER: She was obviously having considerable cardiac failure.

DR. RICHARDSON: She had pericarditis and a friction rub, and probably had ulcers of the bowel. I should like to take exception to something Dr. Butler said. I do not see why the bleeding was due to anemia and high blood pressure. High blood pressure may cause rupture of an artery, but not oozing from the gums and capillary bleeding. Nor does anemia cause it, unless there is a lack of platelets, or except in certain cases of myelogenous leukemia.

DR. BUTLER: You know more about that than I. In my limited clinical experience, purpura in the presence of severe anemia is not uncommon.

DR. AUB: Uremic patients bleed without vitamin C deficiency. One can "pass the buck" by saying it is due to anemia, but they bleed no matter how one explains it.

DR. BUTLER: Rheumatic fever patients may have considerable purpura.

DR. RICHARDSON: That is probably capillary; this is probably capillary bleeding too. I think it is fair to assume that it was due to toxic effect on the capillaries, but after all, this statement does not mean anything.

DR. BUTLER: It is interesting, also, that when I saw this patient, ten days after admission, she did not have any retinitis in spite of the long-standing hypertension. She had constriction of the retinal arteries and thickening of the brachial and radial arteries but no real retinitis.

CLINICAL DIAGNOSIS

Chronic glomerulonephritis.

DR. BRUES'S DIAGNOSIS

Chronic glomerulonephritis.

ANATOMICAL DIAGNOSES

Chronic glomerulonephritis.

Uremia.)

Cardiac hypertrophy, hypertensive type.

Septicemia (*Staphylococcus aureus*).

Endocarditis, chronic rheumatic: mitral valve.

Parathyroid hyperplasia, secondary.

Renal osteitis fibrosa.

Hemorrhages into skin, pleura, lungs, pericardium,

gall bladder, esophagus and ileum.

Acute esophagitis, terminal, uremic.

Acute ileitis, terminal, uremic.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this woman showed a pair of kidneys that weighed 90 gm., one weighing 40 gm., and the other 50 gm.; they had the typical appearance of chronic glomerulonephritis. The surfaces were uniformly coarsely granular, and the cortices were narrow, measuring 2 to 3 mm. Microscopic examination confirmed that diagnosis. Practically every glomerulus was diseased; most of them were completely wiped out and hyalinized,

and others showed characteristic crescents and capsular adhesions. There were foci of tubular dilatation and of atrophy. All parathyroid glands were quite large, weighing together 0.5 gm., which is three or four times the normal weight, and which indicates that the renal insufficiency had been going on for a long time. Further corroboration of that was the fact that the bones showed early osteitis fibrosa. Quite possibly the vertebrae were a little osteoporotic, Dr. Aub, because the intervertebral disks, as you can see from this roentgenogram, are ballooned out, suggesting that the bones themselves were soft. Some marrow spaces were completely replaced by connective tissue, which was also present along some of the bone trabeculae. This is a mild form of the lesions one sees in a child with renal rickets.

There were numerous hemorrhages throughout the body, including the lungs. If these pulmonary hemorrhages became confluent, I wonder if they might produce the picture in x-ray films that the radiologist calls edema associated with nephritis.* There were recent ulcers, probably on a uremic basis, of the small intestine, not of the colon, which is more frequently involved in uremia, and also ulcers in the esophagus. The heart was enlarged, weighing 350 gm., and the left wall was hypertrophied. The murmur was due to a slight but definite degree of stenosis of the mitral valve on a rheumatic basis; but there was no evidence of acute rheumatic infection.

TRANSFUSION WITH BLOOD AND ITS DERIVATIVES AND SUBSTITUTES

THE stimulus of war has brought rapid advances in the practical application of certain fields of medical knowledge. In no field is this more marked than in the field of transfusion. The tremendous feat of wholesale blood collection, which has been carried on throughout the country by the Blood-Donor Service of the American Red Cross, has conditioned the American people to the donation of their blood and has started, it is to be hoped, a movement that will not cease when the war ends. From the blood that has been collected, a large

amount of dried plasma has been made available for shipment all over the world to the armed forces. Every American on the streets today knows that this has contributed materially to the reduction of mortality from wounds on all the fighting fronts. Recent reports indicate that the red cells, previously wasted, may be resuspended, and distributed to civilian hospitals for administration to anemic patients.

Another development from the Red Cross program has been the large-scale fractionation of human plasma into its component parts by methods developed by Cohn and his associates in the Department of Physical Chemistry at the Harvard Medical School. This work was originally started to provide the armed forces with a compact, concentrated blood derivative for emergency use, particularly by highly mobile military troops for whom transportation space is at a premium. Albumin provides the osmotically active fraction of plasma in a very concentrated form, which can be injected rapidly and safely without reactions, and with a rapid increase in blood volume resulting from the drawing of water from the tissue spaces into the blood stream. The possible uses of such an osmotically active and safe concentrated solution in clinical medicine and surgery are manifold.

The fractionation program provides not only albumin for the treatment of shock and conditions associated with hypoproteinemia but also other globulin constituents of the plasma that have important functions. Two of these products have already found useful applications in the clinic. Fibrin foam, which is derived from the clotting elements of the blood, has been shown to have remarkable hemostatic properties for use in neurosurgical operations. The gamma globulin of human serum has been used successfully for the prevention or modification of measles, its advantages being its availability, reproducibility, potency and freedom from substances producing reactions. Further developments of this program should provide the clinician with many new and useful tools — safe because they are derived from human sources — that can be applied to the treatment of disturbances of normal physiology.

The statement by the Subcommittee on Blood Substitutes of the National Research Council, which appears elsewhere in this issue of the *Journal*, indicates that the same type of careful study has been applied to blood substitutes that have been suggested for clinical use. Every physician would do well to read this statement, since it indicates the degree to which good clinical practice is dependent on the basic sciences. Here he will find a clearcut statement of why, from a physicochemical point of view, gelatin cannot be considered to be a satisfactory substitute for either blood plasma or albumin, although it may have some effect in the amelioration of the diminution of blood volume that characterizes surgical shock. The report emphasizes the dependence of the physiologic function of any material on its molecular size and shape. Gelatin molecules range from very long thin ones, giving rise to certain undesirable properties, such as rouleaux formation of the red cells and their rapid sedimentation, to molecules so small that their fairly rapid escape from the circulation makes the effect of gelatin less sustained than that of plasma. Furthermore, it is pointed out that "gelatin solutions probably do not contribute significantly to nutrition," and their influence on "the distribution of plasma proteins between circulating blood and tissues should be further investigated."

Replacement therapy should be directed, whenever possible, to actual replacement of what has been lost. In the case of shock due to hemorrhage, this means whole blood. For reasons of practicality, however, it has been found expedient to supply the armed forces, not with whole blood, but with plasma and albumin, which will sustain the patient until such time as he can receive the needed red cells in the form of a transfusion of whole blood or of resuspended cells. In certain types of shock, plasma alone is lost, and for these, plasma is the ideal replacement fluid.

The products of plasma fractionation are individual proteins used in relatively pure state for the treatment of specific deficiencies. They are blood derivatives, not blood substitutes and have important properties of their own. Thus, albumin, because of its high osmotic activity may restore

blood volume more rapidly than transfusion of an equivalent amount of plasma. The specific properties of purified proteins deserve further exploration, and these blood derivatives give promise of having widespread use in the clinic.

WARTIME POPULATION TRENDS

THE Metropolitan Life Insurance Company, in its April issue of the *Statistical Bulletin*, publishes some interesting comparisons of wartime population trends among various countries. The Axis countries, suffering increasing battle losses, are also less able to replenish their populations at home. On the other hand, the United States and Great Britain have shown marked gains in the natural increase in their populations since war broke out. Germany, home of the "master race" that seems doomed never to achieve its mastery, has become again the land of the deepening shadows.

Germany's natural increase of population, according to this reliable source of information, has been dropping steadily since the war began, with the decline becoming more marked each year that the war continues. Thus the excess of the birth rate over the death rate dropped from 8.1 per 1000 population in 1939 (the best year under the Hitler regime) to 2.9 in 1942, the last year for which official figures are available. The year 1942 had the distinction of revealing the lowest rate of increase in Germany for any year since World War I. It can be assumed that, since 1942, the large-scale bombing of German cities, with evacuation of populations, and the heavier concentrations of men on the fighting fronts have further increased the death rate and decreased the birth rate. The old warning that whom the gods would destroy they first make mad seems to be proving its worth again.

Italy, a member of the Axis until 1943, likewise showed a drop of some 40 per cent in the excess of births over deaths—from 10.1 per 1000 in 1939 to 6.1 in 1942, a decline largely due to a decrease in the birth rate. The other Axis countries have shown similar, though less marked, trends.

Of the occupied countries, a mixed situation seems to have existed. Denmark showed an increase in the

margin of births over deaths through 1942. In the Netherlands, the rate of increase rose after an initial fall. Belgium and France are facing serious depopulation, with death rates exceeding birth rates since 1940.

The crude rate of natural increase in the United States has risen to its highest figure in twenty years, with Canada's growth a close parallel. In England, the excess of births over deaths in 1943 was over 175,000, the highest in fifteen years. Figures are not available for China and Russia, but it may be expected that their usual high fertility will again prevail with their soil freed of invaders and their armies returned to the land.

Regardless of what we may believe regarding the selective limitation of populations for the future, it is obvious that population trends among the United Nations are showing a normally healthy situation as compared with those of Central Europe.

WAR ACTIVITIES

NATIONAL RESEARCH COUNCIL

The following statement was recently released by the Subcommittee on Blood Substitutes of the National Research Council.

On the basis of the extensive earlier literature and the recently accumulated evidence, certain statements can be made concerning gelatin solutions prepared for intravenous use and the chemical, physiologic and clinical properties of such solutions compared with those of plasma.

I. Chemical

(1) Plasma is constituted of molecules whose size is known and is related to plasma function. The plasma proteins may be grouped into a few classes, in each of which the molecules are of uniform size and shape. Gelatin and degraded gelatin solutions submitted for study as transfusion fluids show almost continuous variation in size over a very wide range.

(2) Plasma proteins have diameters close to 36 Angstrom units. Most of the particles of gelatin and degraded gelatin have diameters of about half this value, 18 Angstrom units.

(3) The largest part of the plasma proteins do not deviate greatly from symmetrical shape, though fibrinogen, present to a small extent, has long, rodlike molecules. Gelatin appears to be made up of linear polypeptide chains loosely coiled to give very long molecules.

(4) Degradation of gelatin decreases the number of very long particles, which are responsible for the gelation, much of the viscosity and probably other undesirable effects. Degradation increases the number of very small particles, which are responsible for most of the osmotic pressure, though not for

the colloid osmotic pressure since they diffuse rapidly through membranes.

(5) A standard technic of degradation of gelatin yields solutions of about the same average molecular weight and the same size distribution. The degree of degradation is best measured by the number of potential peptide linkages that are broken. This number can be determined from the osmotic pressure, or more easily from the viscosity, since the intrinsic viscosity of these solutions is proportional to the number-average molecular weight.

(6) Plasma proteins do not readily diffuse through membranes employed in measuring colloid osmotic pressure. A large part of the degraded gelatin solutions submitted for study as transfusion fluids are of such small size as to diffuse readily through such membranes.*

II. Physiological and Clinical

(1) *It must be recognized that, when available, whole blood, plasma or human serum albumin are the solutions of choice to be employed in the treatment of hemorrhage or shock.*

(2) It has been demonstrated that when the precautions recommended to the gelatin industry are taken, pyrogen-free solutions of gelatin can be prepared.

(3) Such gelatin solutions have been given to man without late toxic reactions.

(4) A small percentage of patients have been found to have immediate reactions. Local thromboses are common when certain preservatives are employed.

(5) Injection of the gelatin solutions have been made without evidence of sensitization.

(6) Many repeated injections in animals have been given without evidence, histologic or clinical, of toxicity or irreversible accumulation.

(7) The solutions of gelatin studied have a definite effect in augmenting cardiac output and circulating blood volume in dogs submitted to hemorrhage and in patients suffering from shock due to hemorrhage or skeletal trauma. The evidence at present indicates that gelatin solutions may have a beneficial effect in burns. There is thus clinical evidence that these solutions have a definite, though temporary, effect in relieving the state of shock; therefore it is often necessary to take recourse to multiple injections.

(8) The smaller molecules on which the osmotic effects of gelatin solutions depend are rapidly lost from the blood stream, largely through the kidneys. In this respect the effect of gelatin may be contrasted with that of the plasma proteins, which are not normally lost through the kidneys, but when present in excess form reserves in the tissues.

(9) The longer rod-like particles of gelatin persist in the blood stream and are presumably responsible for rouleaux formation, for the increased sedimentation rate of the red cells and for the changes in the distribution of plasma proteins between the blood stream and the tissues.

III. Limitations and Unanswered Questions

(1) *The solutions gel at about 20°C. and therefore cannot be used in cool or temperate climates in the field.*

(2) *Proper typing of blood following the administration of gelatin solutions may be difficult. This problem should be studied further. It may be essential to warn that a sample of blood for typing should be withdrawn from each patient before the administration of gelatin solution.*

(3) Based on present information, the optimal solution mentioned above shows slow but definite and continued degradation at temperatures encountered in certain theaters of war.

(4) The viscosity of the optimal solution is definitely greater than whole blood.

(5) It is not known whether a solution of this type will impair the return of normal function to kidneys in sustained ischemia or in the case of severe burns or the crush syndrome.

(6) Gelatin solutions probably do not contribute significantly to nutrition. Their only place in medical therapy appears to be to restore a loss of circulating blood volume in acute injury of various types.

(7) The influence of gelatin on the equilibrium in the distribution of plasma proteins between circulating blood and tissues should be further investigated.

*The solution with optimal value in the treatment of hemorrhage and shock examined up to the present time is one of 6 per cent concentration, prepared in saline, and with the general physicochemical characteristics of what is known as the "Knox P-20 type."

Number 3

A TOXIC FACTOR IN EXPERIMENTAL TRAUMATIC SHOCK

JOSEPH C. ALB, M.D.†

BOSTON

MEDICAL investigations are often the product of a number of workers. This is particularly so in these years of war emergency, when groups men co-operate in an attempt to solve problems quickly. Thus, in our search for a toxic factor in shock syndrome, credit for the results is largely due to my associates, who have contributed much to the work and many of the ideas. Those who have worked throughout have been Drs. Austin Brues, Nathanson, Alfred Pope and Paul Zamecnik and Miss Abby Nutt; others have collaborated in part of the work, namely, Drs. Waldo Cohn, René Bos, Cynthia Pierce and Seymour Kety and Miss Dorothy Tibbetts. It is in their name that I make this summarizing report.

The history of the study of traumatic shock need only go back to World War I, when a group of illustrious physiologists studied the mechanisms involved in its production. This brilliant work was well summarized in their reports^{1, 2} and in the book Cannon.³ Many of the physiologic responses that constitute the syndrome of traumatic shock were then delineated, and their cause was ascribed to an assumed but unisolated toxin. Subsequent attempts to isolate the toxin failed.

The period that lay between the two world wars was marked by a reaction against the toxic theory because of convincing studies, largely by Blalock⁴ and Phemister,⁵ which showed the predominant role of local fluid loss in the areas of trauma. And so we entered this conflict in the wise belief that the treatment for shock is transfusion, and readily available plasma has certainly saved many lives. Nothing I may say in this discussion should be construed in any way as detracting from this brilliant page of medical and, indeed, social progress.

I need not describe to this audience the clinical picture of traumatic shock. It is the delayed collapse that follows lacerating or crushing wounds, characterized by the well-known drop in blood pressure and diminution of blood volume.

With the onset of this war we again set ourselves to evaluate the possibility of toxic causative factors in shock. But why should one study the causes of shock? Surgeons say that there are many causes of this syndrome, but that point of view may change with further knowledge. It is true that the syndrome may develop from anesthesia alone, or that it may appear in relatively mild trauma or may be lacking in larger wounds. The reasons for this have not been clear, which merely proves that we have not yet learned its causes. Although shock may develop under diverse circumstances, true precipitating factors are probably not numerous. Depletion of the blood volume by hemorrhage will produce shock through obvious mechanisms, but shock — the so-called "toxic shock" — can also apparently arise from causes and through mechanisms that are less well understood. It is as true of this syndrome as of any disease that thorough understanding of its mechanisms is essential to logical therapy. Anyone who has observed the effects of bleeding and of trauma in animals or man is alert to the different toxic appearances of the traumatized animal. Something other than the large plasma loss appears to be involved. But this factor has appeared elusive. Moon⁶ thought that he had found it by the implanting of autolyzed minced muscle tissue in the peritoneum. Scudder⁷ had the ingenious idea that it was due to liberated potassium from traumatized tissues, though we now think that blood potassium rises only late in the shock picture.

The amount of work that has been done in this country on traumatic shock during this war has been large, and our knowledge of the subject is being well advanced. Much of this work is still unpublished and restricted, so that this discussion will be largely limited to recent publications and to our own unpublished data.

The Annual Oration presented at the annual meeting of the Massachusetts Medical Society, Boston, May 23, 1944.

The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the Massachusetts General Hospital.

From the Medical Laboratories of the Collis P. Huntington Memorial Hospital, Harvard University, at the Massachusetts General Hospital. This is reprint No. 589 of the Cancer Commission of Harvard University.

Professor of research medicine, Harvard Medical School, physician, Massachusetts General Hospital, director, medical laboratories of the Collis P. Huntington Memorial Hospital of Harvard University.

Laboratory studies of traumatic shock have been characterized by the large number of divergent technics and divergent anesthetics in its production. This makes comparison rather difficult. All our observations have been made on dogs with Nembutal given intravenously in amounts sufficient to produce light anesthesia. We have used a new method to produce shock in animals. This was devised as a minimal insult so as not to produce overwhelming shock but to approach the shock state in a more quantitative manner than could be done by technics other than hemorrhage. The method developed by one of our associates, Dr. Nathanson, involves putting tight tourniquets around the two triceps surae, which include the gastrocnemius and soleus muscles. On release of the ties, after five hours, the blood supply becomes re-established and then these muscles swell enormously. The amount of edema that accumulates can be quite accurately estimated by a method, developed by Dr. Kety, of measuring the volume of the limbs.

But fall of blood volume and that of pressure are not the only manifestations of shock that deserve attention. In any experiment it is crucial that other physiologic observations also be made. For blood pressure may be misleading—it may be maintained for a surprisingly long time through vascular constriction, while the shock state may be developing, and then the pressure may fall rapidly, followed promptly by death. Other methods appear essential to judge the early progress of this syndrome—methods that indicate the state of the circulation. Progressive hemic concentration is one of the best technics, as it indicates the actual amount of plasma lost from the circulation. To evaluate the degree of shock we have used technics that originated in the work of one of us (J. C. A.⁸⁻¹⁰) in the last war. It was then shown that when shock is developing the oxygen content of the venous blood is much reduced, that the cardiac output falls, and also that the basal metabolism is reduced owing to the lack of adequate available oxygen. These reactions can all be explained on the basis of a slowing of the blood flow. Our judgment of the degree of shock, therefore, has been based on a fall of cardiac output and blood pressure, a rise in the resistance of the peripheral circulation, mainly that of the arterioles, and a decrease of blood volume. In early experiments we did not obtain all this information, but it has been accumulated in the main body of our recent studies. By means of these technics we were satisfied that we could approach the problem with a quantitative method for producing a minimal shock-producing trauma that would not be so overwhelming as to make study and treatment difficult. We also were able to measure fluid loss in this area progressively, as well as to estimate the beginning and progress of the shock state.

It soon became clear that it would be interesting to study the large amount of fluid that exuded from

the anoxic muscles. A technic for this was arranged by enclosing the muscle in a thin rubber sheath from which the fluid could be collected by simple drainage. After the release of the tourniquet and the re-establishment of blood flow through the muscle, fluid fairly poured out into these investing sheaths. These simple operations could all be done with aseptic precautions, and after our first preliminary experiments, the usual surgical aseptic technics have always been employed.

RESULTS

In the first problem we investigated we sought to find whether the shock state produced a change in the permeability of body cells remote from the area of trauma, that is, whether the cells of organs such as the intestines and the liver allowed electrolytes and proteins to escape more freely than in a normal state. This was an arduous task undertaken by Dr. Brues, in which Dr. Cohn and Miss Tibbetts helped. These data are ready for publication and need no long discussion here. The conclusion was that there was no indication of any consistent shift of intracellular or extracellular water or electrolytes into or out of cells in shock except what occurred locally in the traumatized regions. In the traumatized areas there was evidence that the permeability of cells was considerably altered, so that extracellular salts were allowed to enter and intracellular salts were abnormally lost. Our experiments, however, have shown other characteristics of fluid exchange that appear interesting and important. At autopsy after prolonged shock one finds the intestinal mucosa full of blood, and Dr. Brues has observed that this appears to be markedly increased by transfusion of plasma or blood, showing that transfused fluid may be lost into this area. This indicates that the permeability of these capillaries has been altered by the shock state and that they therefore lose an abnormal amount of fluid.¹¹

It also appears obvious that an abnormal circulation of the body fluids may occur about the area of trauma. Thus, a considerable loss of fluid may exude from the edematous traumatized muscles, sometimes amounting to as much as 200 cc. in five hours. If this fluid is not withdrawn but stays in the legs, it migrates away from the traumatized areas and some of it must be reabsorbed into the circulation. An accessory circulation of fluid is thus established, diffusing through traumatized tissues and being reabsorbed into the general circulation. This may affect the organism as a whole. This circulation, as well as that directly carried in blood vessels and lymph, easily explains the possible widespread effects of the local accumulation of toxic products from trauma. We have established absorption from the anoxic muscle mass by means of radioactive salts. These appear in the blood stream promptly after liberation of the muscle tissue.

have not done this to establish the absorption of free fluid in the wound, but it could easily be done.

The minimal trauma that I have described produced traumatic shock in about a third of the animals. We then measured the fluid that collected from this operation together with the blood that was taken for our various analyses, and compared the incidence of shock in the groups that were subjected to the muscle ties with that obtained in control animals that were bled. There was little difference between the two series. The average incidence of shock in the traumatized animal was higher than in the hemorrhagic controls, but the total loss of fluid in the animals that were traumatized was also slightly higher than that of the control animals. In these observations it appeared that the conclusion of Blalock⁴ and Phemister⁵ was correct and that the shock of trauma was nothing but a large loss of fluid. But we were not satisfied with this conclusion because of the somnolence, lethargy and lack of sensibility to pain seen in patients who have suffered trauma, whereas patients who have simple hemorrhage usually do not exhibit these symptoms so dramatically.

It appeared desirable to investigate the possibility that edema fluids contained some factor toxic to the organism. We therefore collected the fluid that exuded from the muscles that had been made anoxic. This fluid was easily collected aseptically by our technic, although the amount varied markedly in different animals. By using large muscles from which to collect this fluid we could obtain about 200 cc. from one dog. This freshly hemolyzed fluid could then be put into a small test dog to see its effect on blood pressure, diastolic output, peripheral resistance and hemoglobin concentration. By this technic one was increasing blood volume, not decreasing it. If there were toxic, shock-producing factors in this fluid, it had to come along with this increased volume. Interestingly enough, nine out of thirty-two such fluids produced a local traumatic shock in recipient dogs. The results, however, had practically no effect following systemic injection. Drs. Kety and Pope quite wisely inferred from these observations that the toxic factor in these fluids was not constant, and that it therefore probably arose not from the damaged muscle but rather from some extraneous source. This appeared to confirm the old toxic theory of the last war described in Cannon's book³ and the more recent observations of Moon.⁶

We were convinced of a toxic element that was sometimes present in the sheath fluid that exuded from anoxic muscle. We therefore attempted to purify this chemically and, for this purpose, collected more than 2000 cc. of this fluid from a series of 9 dogs. It was collected with sterile precautions in bottles cooled in ice and promptly frozen in

carbon dioxide snow. These fluids were combined, and the mixture proved to be shock-producing to several dogs. It contained some red cells, the hematocrit being about 1 per cent, had a specific gravity of 1.018 and tended to form a thin clot. An analysis of the inorganic salt content of this fluid showed that it contained much intracellular muscle fluid as well as extracellular fluid, for its potassium content was high and its calcium content low. It also contained less protein and more fixed acid than does blood plasma. The toxic factor in this muscle exudate was found to be a large molecule, for it was not dialyzable and was precipitated in the fraction that contained the protein. In this pool of muscle exudate Dr. Zamecnik also found high concentrations of intracellular proteolytic enzymes, and these enzymes were all contained in the fraction of ammonium sulfate precipitate that contained the toxic factor. We therefore sought to find whether these intracellular enzymes might be the factor that produced shock, but subsequent observations proved to Dr. Zamecnik that this was not so, inasmuch as fresh muscle extract that contained the same enzymes in high concentrations did not produce shock. Laborious attempts at purification, therefore, advanced our knowledge only in so far as they showed that the toxic molecule of this accumulation of muscle exudate was in the protein moiety, possibly in the gamma globulins, that it was destroyed by heat, and that its effects were not due to certain enzymes liberated from the damaged muscle. They did not disclose the actual substance that was producing shock in approximately one quarter of the test animals.

In many of these experiments bacteriologic studies of our muscle exudates were made. It soon became clear that, in spite of strict surgical precautions, all the muscle exudates were infected, most of them with organisms of the gas-gangrene group (in muscle exudates from 19 animals, *Clostridia* were found in 13, or 70 per cent). Coliform bacilli were not infrequently present, and in a few experiments *Staphylococcus albus* was found. Bacterial contamination was studied quantitatively to obtain an idea of the number of organisms present. Isolated organisms were also studied by Drs. Dubos and Pierce to see whether they produced toxins. The *Clostridia* were cultured to determine their type, and Dr. Dubos's laboratory found them to be the Welch bacillus (*Clostridium perfringens*).

When the number of these organisms was compared with the toxicity of the fluids, it became clear that the three fluids that produced shock in the series were among those that had the highest concentrations of *Clostridia*. In order to test this finding we assured the presence of an ample infection by injecting a culture of *Clostridia* into the triceps surae muscles at the time of ligation. In a series of 3 animals we injected *Clostridia* that had been isolated in previous experiments. These

muscles produced large quantities of fluid in which the amount of organisms varied as the fluid collection progressed. When the resulting heavily infected muscle fluids were injected into recipient animals, they produced profound shock when only one third of the usual amount of fluid was given. Removal of most of the organisms in the injected fluid was accomplished by high-speed centrifugation. The toxic factor did not appear to be the organism, for the supernatant fluid was equally toxic, whereas injected organisms resulted only in producing fever. A single similar observation was described in a report by the British Medical Research Committee¹² during the last war, in which edema fluid from the injection of *Vibrio septique* produced prompt and fatal shock. We next sought an antidote. Polyvalent *Clostridia* antitoxin was given to a dog a few minutes before injecting an extremely toxic sheath fluid. No shock developed. Our observations indicated that an anoxic muscle was an excellent medium for the growth of *Clostridia* and for the formation of its toxins.

We became interested in ascertaining why our tissues were so frequently contaminated with *Clostridia*. A dog's skin was prepared by shaving and thorough scrubbing with soap and water, followed by ether and alcohol solution, and then painting with strong iodine solution. After this strenuous preparation *Clostridia* could still be found on the intact skin. When Dr. Nathanson used electro-surgical technics with the greatest precaution, *Clostridia* were still found in the muscles deep in the normal anesthetized dog's leg. We are not sure that they exist there normally, for there is a possibility that spores may be carried into the muscle, but it is clear that they are frequently present in muscles in any traumatizing procedure. Our evidence, as well as confirmatory evidence,¹³ demonstrated that *Clostridia* are practically constantly present deep in the skin of dogs. The presence of *Clostridia* has been noted before in dog muscles by Roome and Wilson,¹⁴ although they thought them to be nontoxic. It is possible that they do not produce toxins even though they are present in the normal muscle, and that in traumatized muscles they can multiply and produce their usual toxins only in these relatively anaerobic conditions. This discussion becomes only of academic interest in these observations. The important fact is that the organisms are frequently present in traumatized dog muscle, and whether they are normally present or a contaminant makes little difference in the interpretation of our results. Dogs are the animals usually used for the study of traumatic shock, and the contamination of traumatized muscle by these naturally occurring *Clostridia* appears to us to be significant and to explain our varying cases of shock from muscle juice.

We next turned to the study of purified *Clostridia* toxins. These were obtained through the kindness

of Dr. Milan Logan, who furnished us with the toxins of *Cl. perfringens* and of *Cl. oedematiens*. Injected intramuscularly these toxins produce different reactions. The Welch bacillus (*Cl. perfringens*) produces a great deal of local edema, possibly because its toxin is a lecithinase and therefore has a destructive effect on cell membranes. With this accumulation of fluid in the muscles there develop all the manifestations of shock that we have been determining: a reduced cardiac output, increased peripheral vascular resistance, a fall of blood pressure, a reduced blood volume and its accompanying increased hematocrit, and a lowered venous pressure. All these manifestations may be explained by the local effect of the toxin. We have not yet established whether there is a more general toxic action. When given intravenously this toxin produces marked hemolysis, and although shock is produced, it is different in this regard from our other experiments. We have observed, however, that moderate hemolysis is a common manifestation of shock in dogs, thus confirming the observation of Coonse et al.¹⁵

Cl. oedematiens toxin does not produce edema promptly when given intramuscularly, and intravenously it results in gradual shock without hemolysis. Following the administration of fatal doses there is often no immediate fall of blood pressure. The cardiac output declines gradually to very low levels, with an increased peripheral vascular resistance. The blood pressure falls terminally. At death there is intense congestion of the duodenum and small intestine, the liver is congested, and the adrenal medulla may be hemorrhagic. These findings are analogous to our pathologic findings in shock, except for the hemorrhagic adrenal glands.

The mechanism is known by which the Welch bacillus produces some of its effects.^{16, 17} Macfarlane and Knight¹⁸ showed that the so-called "alpha toxin" is an enzyme—a lecithinase that breaks down lecithin into smaller molecules. Lecithin is a constituent of cell surfaces, so that destructive effects on capillaries or muscle cells can be understood, as well as the hemolyzing effect on red cells. A change of cell surface usually means a change in cell permeability, and so it is possible to explain the large effusions in the muscles where Welch bacillus toxin is placed. A similar enzyme is present in only small amounts in *Cl. oedematiens* toxin.¹⁹ But this is not the only enzyme, for there is also present another group of enzymes called "hyaluronidases" or mucinases, or the so-called "spreading factor," that hydrolyze hyaluronic acid. This acid is found in connective tissue, and the enzymic effect of destroying it results in a great increase of diffusibility through tissue and therefore in the spread of extracellular fluid and bacteria. One may thus explain the great edema not only its presence adjacent to the area of toxic injection but also its widespread diffusion.

Has this work any significance in traumatic shock in the hospital emergency ward or at the front? In a series of eighteen elective orthopedic operations by Dr. Carroll Larsen and others, no Clostridia were found in human muscles. We must therefore decide that any Clostridia present in wounds are introduced at the time of injury. War wounds have been shown to have more than 30 per cent contamination with Clostridia, frequently without the appearance of detectable gas.²⁰ Such Clostridia, introduced into tissues that have not harbored them before, might be expected to be particularly likely to form toxins. The slow onset of shock seen in some of the wounded agrees with the length of time necessary for the proliferation of bacteria and the formation of their toxins. The importance of such organisms in the shock of war wounds appears to be a problem in regions of combat most urgently needing evaluation.

Our experiments have shown again the great importance of a loss of plasma fluid as a cause of traumatic shock, but they also indicate the importance of infection as a toxic factor. Clostridia that lurk normally in the dog multiply rapidly and produce their toxins in the excellent surroundings of traumatized anoxic muscles. The effects there will certainly accentuate the local fluid loss and so give a summation of effects. The toxin of *Cl. oedematiens* in the blood stream produces a shocklike state, but the mechanism is not yet clear to us. The time relations are satisfactory for allowing organisms to grow and for the onset of delayed traumatic shock. We think that the evidence is quite convincing that infection is the so-called "toxic factor" in traumatic shock in dogs.

We do not know as yet how widespread are the effects of the toxin. In our observations in the shocked animal it is clear that elevation of blood volume by transfusion is followed by markedly accentuated local fluid loss in the upper intestine and liver and lungs, as well as in the area of trauma. Such changes in permeability may be due to simple anoxia or to circulating bacterial toxins. This is a question we are in the process of trying to answer

There may be other ways to poison the capillaries and venules in the way found characteristic of shock. It is not surprising that long anesthesia should be one such, and that the anoxia of hemorrhage should be another. We have searched hard for other toxins at the area of trauma, but we have not found them. In our experiments, fluid loss and infection appear to account for our incidence of shock. From a practical point of view it is good to have it so, for one can act constructively about them because methods for alleviating them both are available.

RENAL FAILURE SIMULATING ADRENOCORTICAL INSUFFICIENCY*

GEORGE W. THORN, M.D.,† GEORGE F. KOEPF, M.D.,‡ AND MARSHALL CLINTON, JR., M.D.§

BOSTON AND BUFFALO

IT HAS been shown that the hormone of the adrenal cortex aids in the maintenance of a normal state of hydration by increasing the renal tubular reabsorption of sodium, chloride and water.¹⁻⁴ Hence, in the absence of this hormone, as in Addison's disease, excessive sodium, chloride and water are eliminated by the kidneys and, as a consequence, dehydration, hemoconcentration, hypotension and ultimately collapse may ensue. Theoretically, one might expect to encounter at some time a type of renal tubular damage or incapacity that would prevent the adrenocortical hormone from exerting

like state presenting signs and symptoms indistinguishable from those of acute adrenal insufficiency occurring in patients with chronic nephritis and normal adrenal glands has not been reported. The present study is concerned with a report of two patients who, on admission to the hospital, were considered to be suffering from acute adrenal insufficiency. Subsequent studies over a period of two to four years, including post-mortem examinations, proved that the metabolic changes in the body followed renal rather than adrenal disease. These cases are of interest not only because of the

FIGURE 1.

its usual effect on the tubular reabsorption of sodium and chloride (Fig. 1). Under these circumstances a clinical picture simulating the electrolyte disturbance seen in Addison's disease might be presented by a patient with intact, normal adrenal glands.

Hypochloremia and dehydration have been described in patients with renal disease, and the occurrence of this phenomenon in patients with uremia without edema is well known.⁵ To our knowledge, however, the clinical picture of a shock-

physiologic implications that they present but also because therapy directed toward correcting the metabolic disturbances resulted in the rehabilitation of these patients for a life of economic usefulness for periods of two to four years.

OBSERVATIONS

It is of interest to note the close parallelism that occurred in the clinical courses of these patients.

Both were young adults without clinical evidence of previous renal impairment, and both were admitted in a state of collapse with hemoconcentration, dehydration and hypochloremia. Since protein and formed elements were not present in the urine of either patient, both patients were treated initially with sodium, chloride and glucose solutions as well as adrenocortical hormone in an attempt to correct the apparent acute adrenocortical insufficiency.

§Research fellow in medicine, Harvard Medical School; junior associate in medicine, Peter Bent Brigham Hospital.

Dramatic improvement followed the therapy outlined above. Following restoration of plasma volume and blood pressure, however, azotemia persisted and kidney-function tests revealed marked and persistent high-grade renal insufficiency. Ultimately, it was shown conclusively that, whereas sodium, chloride and water were lifesaving, adrenocortical hormone preparations were of no value in the treatment of these patients. Sustained clinical improvement—for two and a half to four years—accompanied adequate sodium chloride and sodium bicarbonate therapy. Lastly, moderate hypertension, edema and moderate proteinuria developed terminally in both patients.

CASE REPORTS

CASE 1. J. L. (Johns Hopkins Hospital 155764; P. B. B. H. M62361), a 21-year-old man, was admitted to the University of Pennsylvania Hospital on October 18, 1938, complaining of nausea, weakness and vertigo. He had felt well until 1 month prior to admission, when he noted gradually increasing nausea after meals. One week later, he became aware of weakness and vertigo, which was present at first only on exertion but later whenever he was in the erect position. In addition, he had had muscular twitching for several weeks.

At the age of 6 months the patient had a severe throat infection, which was followed by subsequent attacks of less severity. Following tonsillectomy and adenoidectomy at the age of 8, he experienced no further difficulty. There was no history of any other significant childhood illness. His health records at a private school and at a technical school were good. The family history was noncontributory.

During his childhood the patient had noted polyuria and usually had to urinate once during the night. When he was 17 years of age, his appetite became finical. At about that time he found it difficult to arouse himself in the morning because of a sensation of being "doped." In addition, he noted occasional cramps in the legs and feet. A profuse, mucoid postnasal discharge began to manifest itself, and this frequently induced morning nausea and emesis. All these symptoms persisted in varying degree throughout the illness.

Physical examination on admission disclosed a well-developed, freely perspiring young man who appeared chronically ill and evidenced recent weight loss. The blood pressure was 64/46. Generalized sporadic, involuntary, muscular twitchings accompanied by occasional bouts of hiccough were present. The patient was drowsy but aware and intelligent. The skin over the face, body and extremities was markedly freckled, but no abnormal pigmentation was present on the skin or mucous membranes. The axillary and inguinal lymph nodes were slightly enlarged. The ocular fundi appeared entirely normal. There was a uremic odor to the breath. In the right tonsillar fossa a small amount of lymphoid tissue was present. The pharynx was moderately inflamed and a mucoid postnasal discharge was present. The voice was nasal. Examination of the chest revealed no abnormalities. The heart was of normal size, and no murmurs were noted. No abdominal masses or organs could be felt. There was no tenderness in the costovertebral angles. Neurologic examination was not remarkable except for a positive Chvostek's sign.

Laboratory examination at this time disclosed a hemoglobin of 75 per cent and a red-cell count of 4,100,000. Numerous urinalyses disclosed a specific gravity that varied from 1.005 to 1.010. *No albumin or formed elements were present in the urine at any time.* A phenolsulfonphthalein test showed 5 per cent excretion in 2 hours. The blood urea nitrogen was 96 mg. per 100 cc., the serum carbon dioxide combining power 15.0 millimoles per liter, and the chloride 84.8 milliequiv. per liter.

Following the administration of glucose and saline solution intravenously the patient felt greatly improved. Five days later the blood urea nitrogen had fallen to 84 mg. per 100 cc. and the serum chloride had risen to 104.4 milliequiv. per liter. At that time the patient developed a toothache, began to

vomit and experienced pronounced malaise. Chemical determinations following the extraction of a badly infected tooth disclosed a rise in the blood urea nitrogen level to 145 mg. per 100 cc., a fall in the serum carbon dioxide combining power to 12.0 millimoles per liter and a fall in the serum chloride level to 88.7 milliequiv. per liter. Administration of adrenocortical extract intravenously, sodium lactate and glucose solution induced temporary improvement. On November 14, the patient was transferred to the Johns Hopkins Hospital.

Physical examination on admission to this hospital was essentially the same as that reported above except that the blood pressure had increased to 96/54 and the patient appeared less acutely ill. The hemoglobin was 10.8 gm. per 100 cc., the red-cell count 2,000,000, the hematocrit (volume of packed red blood cells) 26 per cent, and the white-cell count 4920, with a normal differential count. The serum nonprotein nitrogen was 112 mg., the total protein 6.0 gm., the blood sugar 86 mg., and the cholesterol 190 mg. per 100 cc. An electrocardiogram was normal. Roentgenographic examination of the heart, lungs, gastrointestinal tract (barium meal) and abdomen (flat plate) disclosed no abnormalities.

The patient was given 30 gm. of sodium chloride (1.5 per cent solution) and 10 cc. of adrenocortical extract intravenously each day. Dramatic subjective and objective improvement followed within 2 days. After 4 days on this regimen the blood nonprotein nitrogen was 63 mg. and the total protein 5.9 gm. per 100 cc., the serum sodium 147.2 milliequiv., the chloride 104.8 milliequiv., the potassium 4.9 milliequiv., the carbon dioxide combining power 24.4 millimoles, and the phosphorus 2.6 millimoles per liter. The urea clearance was 10 per cent of the predicted normal. A phenolsulfonphthalein test showed increased excretion to a total of 15 per cent in 2 hours.

It was impossible to state whether the dramatic improvement that had occurred could be ascribed to the administration of the large doses of sodium chloride, to treatment with adrenocortical hormone or to both. To determine more accurately the agent responsible for improvement, the dose of sodium chloride was reduced from 23 to 3 gm. daily for a 5-day period. Despite the continued administration of adrenocortical extract and 20 mg. daily of desoxycorticosterone acetate (a relatively large dose), the previous symptoms of lassitude, nausea and vomiting returned within 2 days. The blood nonprotein nitrogen rose from 65 to 128 mg. per 100 cc.; the serum sodium fell from 145.6 to 131.0 milliequiv., and the serum chloride from 107.8 to 97.2 milliequiv. per liter. The daily administration of 23 gm. of sodium chloride was reinstituted and was again followed by an alleviation of symptoms and a prompt improvement in the chemical findings. At that time the adrenocortical hormone therapy was discontinued. No relapse occurred, and so far as could be determined the patient did as well on sodium chloride therapy alone as he had on the combination of adrenocortical extract and sodium chloride.

The patient was able to leave the hospital for the Christmas holidays, and during this interval he took 25 gm. of sodium chloride daily by mouth without other therapy. On this regimen he was able to be up and about for 12 to 16 hours a day without excessive fatigue. On January 5, 1939, he was readmitted for further study. The blood pressure was 124/80. During this hospital stay he was maintained in good condition with 25 gm. of supplementary sodium chloride daily. The addition to this regimen of 20 mg. of desoxycorticosterone acetate daily (an excessive dose) for 6 days had little effect on the body weight, plasma volume, serum electrolytes and urinary excretion of sodium and chloride (Figs. 2 and 3), in contrast to the striking effect following the administration of a similar dose to patients with Addison's disease and normal human subjects.⁶ The administration of 2 cc. (200 units) of parathormone was followed by no increase in the urinary excretion of phosphorus (Fig. 4). Furthermore, Pitressin in doses of 0.25 cc. every 4 hours for a 48-hour period failed to reduce the volume of urine significantly and was not accompanied by any gain in body weight (Fig. 5). Studies of the urinary excretion of ammonia indicated extreme limitation of ammonia formation. Since the carbon dioxide combining power of the blood had gradually fallen from 24.4 to 17.2 millimoles per liter, sodium bicarbonate was given by mouth in addition to supplementary sodium chloride.

During the next 2 years the patient was given large doses of enteric-coated sodium chloride tablets (10 to 20 gm. daily) and sodium bicarbonate (5 to 10 gm. daily), administered orally. He felt well, and despite a persistent gradually increasing anemia and a blood level of nonprotein nitrogen ranging from 70 to 130 mg. per 100 cc., he was able to work full time and occasionally to play golf. Episodes of nausea and vomiting, usually occurring in the morning, were relieved by intravenous infusion of sodium chloride solution, which he obtained at his local hospital en route to work. During this period he frequently returned to the Johns Hopkins Hospital for observation. No great change in the clinical status was encountered, except a slight but progressive increase in the degree of anemia. It was also noted that it became increasingly difficult to induce a significant

increased. The heart, which on all previous examinations had been below normal size, was slightly but definitely larger than normal. Urinalysis showed a fixation of specific gravity (1.008) and a + test for albumin. No formed elements were noted. The red-cell count was 1,800,000, the hemoglobin 5.8 gm. per 100 cc., and the hematocrit 24 per cent. The white-cell count was 9300, with a normal differential count. The following chemical findings were noted: nonprotein nitrogen 253 mg., urea nitrogen 187 mg., and total serum protein 5.9 gm. (albumin 3.3 gm.; globulin 2.6 gm.) per 100 cc.; serum sodium, 135 milliequiv., chloride 98 milliequiv., carbon dioxide combining power 20.0 millimoles, calcium 3.9 milliequiv., and phosphorus 4.5 millimoles per liter; and alkaline phosphatase 2.3 Bodansky units per 100 cc. The excretion rate of 17-ketosteroids was 1.6 mg. per 24 hours.

FIGURE 2. Studies on Sodium and Chloride Balance in Severe Renal Insufficiency During Desoxycorticosterone Acetate Therapy (Case 1).

drop in the blood nonprotein nitrogen level by the administration of sodium chloride solution intravenously.

Additional renal-function tests were carried out during this period in an effort to evaluate the clinical situation and to determine the nature of the underlying pathologic process. All tests performed indicated a marked reduction in renal function. Repeated urea-clearance tests gave values ranging from 5 to 15 per cent of normal. The endogenous creatinine clearance averaged 29.5 cc. of plasma per minute, as compared to a normal of 100 to 120 cc. The sulfanilamide clearance was approximately 12 per cent of the expected normal. The tubular reabsorption (T_m) of glucose was 75 mg. per minute, as compared with the normal rate of over 500 mg. Cold-pressor and mental-effort tests disclosed an active, moderately labile vasomotor system.

In April, 1942, the patient while at work crushed his right thumb, which became infected and failed to heal. Within a month weakness and nausea became pronounced. Because of this the patient was admitted to the Peter Bent Brigham Hospital on July 22.

Physical examination at this time differed from the previous examination as follows. The blood pressure was definitely elevated, being 144/90. Edema of the face and extremities was present. The uremic odor of the breath had

Because of the presence of edema and hypertension, it was necessary to reduce the dose of sodium chloride. The patient was placed on a high-carbohydrate, low-protein and low-fat diet and was given 5 gm. of sodium chloride and 2 gm. of sodium bicarbonate daily. He was repeatedly transfused. Despite these measures, the course was one of gradual decline. The mucopurulent postnasal drip increased. The blood pressure fluctuated between 130/80 and 164/95. The white-cell count rose gradually to 33,000. The patient became unable to take any appreciable quantity of nourishment by mouth, so that all medication was administered parenterally. The blood urea nitrogen level gradually rose to 304 mg. per 100 cc.; the serum sodium level fell to 124 milliequiv., and the carbon dioxide combining power to 8.0 millimoles per liter. Twenty-six days after admission, the patient lapsed into coma and died.

Autopsy (Dr. S. Burt Wolbach). The body was that of a normally developed but somewhat poorly nourished young white male who appeared to have had a chronic debilitating disease. The skin was pale and of fair complexion; the hair was red. There were ecchymoses, averaging 1 to 2 cm. in diameter, over both forearms and lower legs. The mouth showed a grayish-brown, granular exudate, with an ulcer 1 cm. in diameter on the buccal cavity opposite the last

olar tooth on the right. There was marked pallor of the mucous membranes and slight cyanosis. Examination of the peritoneal cavity showed the kidneys to be somewhat small on palpation but in their usual position. The bladder was distended to the level of the umbilicus and was estimated to contain 750 cc. of urine, which was pale and rather clear. The pericardial surface was smooth, lustrous and without exudate. The heart was somewhat enlarged and reached to the midclavicular line. The pleural cavity contained 50 cc. of clear amber solution. The surface was grayish red in color, lustrous and without exudate. The heart weighed 400 gm. and was grossly enlarged, most of the enlargement being noted in the left ventricle. The valves were not dilated. The external contour was of the usual conical shape. On the anterior surface of the left ventricle

tures, none of which appeared to communicate with one another. A few submucosal hemorrhages were found in both pelvis. The genital organs were normal. The aorta contained a minimal degree of atheromatous change. The superior vena cava and its tributaries were normal. The trachea was normal; the thymus gland was not identified; the thyroid gland weighed 17 gm.; the parathyroid glands were markedly increased in size, the largest measuring 2 by 1 cm. and the smallest 1.5 by 1 cm. Together the four parathyroid glands weighed 5.7 gm.; they were in their normal location and were grayish yellow. The cut surface revealed a tortuous, smooth parenchyma. The lymph nodes were not remarkable. The bones and bone marrow were normal. No abnormalities of musculature were noted.

Microscopically, the renal architecture was markedly

FIGURE 3. Ineffectiveness of Desoxycorticosterone Acetate Therapy in Renal Insufficiency (Case 1).

in the region of the apex there were a few small infiltrations of the myocardium with what appeared to be whitish strands of fibrous tissue. Atheromatous changes of a minimal degree were present in the coronary arteries. The lungs and spleen were not remarkable. The alimentary tract was normal except for a few areas of submucosal hemorrhage, from which no actual bleeding point could be demonstrated. The pancreas weighed 95 gm. and was otherwise normal. The liver weighed 1800 gm. and was normal. The gall bladder and duct were normal. Each kidney weighed 140 gm. No developmental abnormalities of blood vessels or ureters were present. Everywhere over the surface were seen cysts varying from 2 to 40 mm. in diameter. The cyst walls were translucent, and yellowish-colored fluid could be seen within the cysts. The kidney capsule was stripped with difficulty. The external surface of the kidney following stripping was of a mottled gray, white and red tissue being interspersed among the various cysts. This tissue was of a finely and uniformly granular appearance. No gross scars were found. The cysts were present throughout the kidney substances, and among them were irregular strands of parenchyma. In general, the cortex was not more than a few millimeters in thickness, but in a few places measured as much as 6 mm. Tubular striations could not be identified. There was great distortion of architecture everywhere; probably four fifths of the surfaces cut in any direction consisted of cystic struc-

altered by the presence of numerous cystic areas, extensive scarring and extreme dilatation of many of the tubules. There was an irregular increase in the capsular connective tissue. The capsule contained numerous, large, well-filled vascular spaces and in some areas a fair amount of adipose tissue. The inner aspect of the capsule was continuous with the diffuse scarring encountered throughout the renal substance, widely separating the remaining tubules and glomeruli. In many areas it was dense and hyaline, but in others it was fibrillar and appeared to be more recently formed. For the most part, the tubules were lined by low cuboidal or flattened, atrophic epithelium. They were decreased in size and in rare instances contained densely basophilic colloid casts or granular protein material and cellular debris. A striking feature was the separation of the tubules from the capillaries in the scar tissue. Only in a minority of instances did the tubules within the scar tissue closely approximate the capillaries. Many of the latter were well filled with blood elements. Diffusely and irregularly infiltrating the fibrous tissue were moderately large numbers of lymphocytes and plasma cells. Only rare scattered polymorphonuclear leukocytes were present in the interstitial connective tissue.

The glomeruli were decreased in total number in the sections, and those identified showed rather wide variations in size and shape, as well as in the degree of intrinsic glomerular

damage. Throughout the sections were many completely scarred glomeruli, most of which showed scarred adhesions between the fibrosed glomerular tufts and the thickened capsular connective tissue. A fair number of the remaining

capillary tufts were only moderately well filled with blood in most instances.

Throughout all the sections there were large areas in which the tubules showed extraordinary dilatation. These were

FIGURE 4. Ineffectiveness of Parathormone Therapy in Renal Insufficiency (Case 1).

glomeruli showed evidence of past inflammation. There were adhesions between the glomerular tufts and the capsule, as well as some focal scarring in single capillary tufts. For the most part, the pericapsular connective tissue showed

lined by moderately low columnar or cuboidal epithelium, but for the most part, they were empty or contained finely granular acidophilic protein precipitate. In some instances, adjacent, greatly dilated tubules appeared to be confluent

FIGURE 5. Ineffectiveness of Pitressin Therapy in Renal Insufficiency (Case 1).

a diffuse laminar thickness. There was no evidence of an active inflammatory process. Only a few glomeruli were free from adhesions or capsular scarring. The residual

with the formation of irregular cystic areas. Rarely beneath the tubular membrane there were trapped masses of material that had a basophilic staining tendency and suggested cal-

ium deposition. This was accentuated in the sections stained with hematoxylin and eosin. In several areas, both within the tubules and just beneath the tubular epithelium, there were seen masses of refractile, elongated crystals arranged predominantly in a stellate pattern. For the most part, the scar tissue surrounding the greatly dilated tubules was more fibrillar and better vascularized than that surrounding the atrophic tubules previously described.

Also seen throughout the sections were large cystic areas lined by low cuboidal or flattened epithelium and surrounded by scar tissue. These cystic areas were, for the most part, empty, but a few of them contained fine granules of acidophilic precipitated material. These cysts were encountered in the cortex and medullary regions alike, but the greater number appeared to be just beneath the cortex at the juncture of what in a normal kidney would have been cortical and medullary tissue.

The caliceal and pelvic epithelium included in these sections was fragmentary. Beneath this epithelium there was abundant dense connective tissue that had the lymphoid infiltration seen elsewhere in the kidney substance. The arteries and arterioles showed only slight degrees of intimal thickening and hyalinization. Nowhere was there necrotizing arteriolitis or hemorrhage.

The right adrenal gland weighed 16.5 gm. and the left 24 gm. They were of normal consistence. On section, the cut surface of the adrenal cortex was golden yellow. The medulla was pale gray, and some increase in its thickness was present. No cortical adenomas were noted. The left gland was distorted at one pole, where a large spherical nodule was present. On inspection this did not seem to be a neoplasm.

All sections of the parathyroid glands showed an extraordinary degree of hyperplasia. The hyperplastic cells were in clusters and cords that were separated by delicate reticular connective tissue. In many of the cords the cells were heaped up on each other so that no lumens were present. In many instances, however, the cells were arranged around irregular central lumens. In scattered areas throughout all the sections acinous formation was the predominant feature. In one section a few acini were dilated and filled with acidophilic granular substance. The cell composition of the cords or acini varied from area to area. The predominant cells had clear, colorless cytoplasm and distinct cell boundaries and were moderately large. There were numerous interspersed cells with clear or faintly granular acidophilic cytoplasm. The capillaries coursed in the reticular strands of interstitial connective tissue. Most of these were collapsed and poorly filled. In some areas the interstitial connective tissue was increased in amount and hyalinized, and included in these regions were scattered hemosiderin-laden macrophages. A few moderately large vascular channels were well filled with blood cells. Thin trabeculae dividing the hyperplastic glands in roughly lobular architecture appeared to be derived from perivascular connective tissue.

CASE 2. B. P. (Buffalo General Hospital 132264; Johns Hopkins Hospital 230057), a 21-year-old woman, was admitted to the Buffalo General Hospital on February 27, 1940, in coma. She had been in excellent health until August, 1939, when she vomited for the first time. This was followed by repeated attacks of emesis of practically all food ingested. Progressive weight loss and generalized weakness occurred throughout September. The patient felt well during October and November, but in December emesis recurred for 1 week. In February, 1940, the patient again had persistent emesis, became progressively drowsy, and lapsed into coma, at which time she was admitted to the hospital.

The family history was noncontributory. The patient had two siblings who were in excellent health. Her father had a positive serologic reaction but no history, symptoms or physical signs of syphilis.

The patient had had the usual childhood illnesses, but was considered by her parents to have been an unusually healthy child. A tonsillectomy had been performed when she was 12 years old. The blood pressure at that time was normal, and routine preoperative urinalysis revealed no abnormal findings. For 3 or 4 years prior to the onset of her present illness the patient had had nocturia at least once each night. She was the smallest member of her family, and it was thought that she grew less rapidly than her brother and sister. The menstrual history was entirely normal.

Physical examination on admission revealed an acutely ill, emaciated, pale, comatose young woman turning her head from side to side. The rectal temperature was 99°F., the pulse was 120 and weak and thready, and the respirations were shallow and rapid. The blood pressure was 35/0. The skin was dry and the turgor was poor. The eyeballs were soft and the pupils were fully dilated. Examination of the retinal arteries disclosed a slight increase in tortuosity; the fundi were otherwise negative. The chest was clear and resonant. The heart was not enlarged; the rhythm was regular and no murmurs were audible. The heart sounds were distant. The abdomen was soft and no masses were palpable. Pelvic examination revealed no abnormalities. The rectal sphincter tone was good. Knee jerks and ankle jerks were active, and no abnormal reflexes were noted.

Treatment was instituted immediately following admission. Intravenous administration of 5 per cent glucose in physiologic saline solution was begun at once and followed by 1000 cc. of whole blood. The patient was placed in an oxygen tent in the modified Trendelenburg position. The response to this treatment was prompt and dramatic. The blood pressure rose within a few hours to low normal levels and the patient regained consciousness. The following morning (12 hours after admission) she looked and felt greatly improved.

Laboratory examination disclosed a red-cell count of 3,600,000 and a hemoglobin of 7.5 gm. per 100 cc. The white-cell count was 12,350, with a normal differential count. The Kahn and Wassermann reactions were negative. The urine had a specific gravity of 1.010 and a trace of albumin. The chemical findings were as follows: blood sugar 191 mg. per 100 cc.; blood urea nitrogen 249 mg. per 100 cc.; whole-blood chloride 50.8 milliequiv. per liter; serum carbon dioxide combining power 14.1 millimoles per liter, and serum sodium 115 milliequiv., potassium 5.3 milliequiv., calcium 4.1 milliequiv., and phosphorus 6.5 millimoles per liter. The serum albumin was 5.7 gm. and the globulin 1.8 gm. per 100 cc. The whole-blood creatinine was 15.2 mg., the uric acid 8.4 mg., and the cholesterol 156 mg. per 100 cc.

Despite the unusual degree of renal impairment evidenced by the chemical findings, the patient was able to eat fairly well and clinically appeared well. Within 1 week following admission she was up and about the hospital ward. Repeated urinalyses disclosed a fixation of specific gravity at 1.010 and an occasional trace of albumin. *At no time were formed elements present in the urine.* A phenolsulfonphthalein test showed a total excretion of 10 per cent in 2 hours.

Following the administration of liberal amounts of sodium chloride solution the blood urea nitrogen level fell to 195 mg. per 100 cc. and the whole-blood chloride rose to 89.7 milliequiv. per liter. The patient was discharged approximately 3 weeks after admission, feeling reasonably well. At the time of discharge the blood pressure was 100/80.

Following discharge, no specific therapy was given. The patient remained fairly well until May, 1940 (6 weeks later), when she again began to vomit. Emesis occurred in the morning. It became progressively worse and necessitated readmission on June 12. The blood pressure was 106/60, the rectal temperature 99.2°F., the pulse 120, and the respirations 25. The patient was alert. The fundi showed no abnormalities. The remainder of the physical examination was essentially the same as on the previous admission. The outstanding laboratory findings were as follows: red-cell count 3,500,000, and hemoglobin 72 per cent; blood urea nitrogen 264 mg. per 100 cc.; and serum calcium 4.4 milliequiv., serum phosphorus 4.4 millimoles, whole-blood chloride 57.6 milliequiv., serum chloride 71.2 milliequiv., serum sodium 108.7 milliequiv., and serum potassium 4.1 milliequiv. per liter. Repeated urinalyses showed a specific gravity fixed at 1.010, an occasional trace of albumin and *no formed elements.* Roentgenographic examination of the kidney area following the intravenous administration of Diodrast failed to demonstrate the presence of any dye in the renal pelvis.

Immediately following readmission the patient was transfused with 500 cc. of whole blood. Four grams of supplementary sodium chloride was given each day. The intramuscular administration of 5 to 10 mg. of desoxycorticosterone acetate daily for a 2-week period had no significant effect on the renal excretion of chloride. Treatment with 16 gm. of sodium chloride and 5 gm. of sodium bicarbonate daily was then instituted. After 8 days on this regimen the patient developed slight peripheral edema and had several convulsive seizures. Chemical examinations at this time re-

vealed a fall in the blood urea nitrogen level to 42 mg. per 100 cc. and a rise in whole-blood chloride to 94.6 milliequiv. per liter. The plasma carbon dioxide combining power was 7.3 millimoles, the serum calcium 5.0 milliequiv., and the phosphorus 2.7 millimoles per liter; the serum albumin was 2.7 gm., and the globulin 1.9 gm. per 100 cc. Treatment was discontinued for 2 days and the convulsive seizures did not recur. The patient was then given 12 gm. of sodium chloride and 3.6 gm. of sodium bicarbonate daily by mouth, and subjective and objective improvement followed. She was discharged in September.

The patient remained relatively well, aside from occasional bouts of morning nausea and vomiting, and was able to do part-time work. Her nausea was controlled by the intravenous administration of physiologic sodium chloride solution. In addition, frequent blood transfusions were given in an effort to correct the anemia. Medication was gradually increased to 15 gm. of sodium chloride and 6 gm. of sodium bicarbonate daily. During that period the blood urea nitrogen level ranged between 73 and 111 mg. per 100 cc. In May, 1941, the patient was admitted to the Johns Hopkins Hospital for further study.

Physical examination on admission disclosed a moderately well-nourished, somewhat underdeveloped young woman. The blood pressure was 128/80. No abnormal skin or mucous membrane pigmentation was noted. The retinal vessels were moderately tortuous, with more than normal shimmer to the retina. The thyroid gland was palpable. The heart was not enlarged. A low-pitched systolic bruit was present over the precordium. The kidneys were not palpable. The extremities were not remarkable. No edema was present. The deep tendon reflexes were hyperactive; there was no Chvostek's sign.

Urinalysis showed a clear urine with a specific gravity of 1.010 and a trace of albumin but no formed elements. The red-cell count was 2,700,000, the hemoglobin 8 gm. per 100 cc., the hematocrit 24.1 per cent, and the white-cell count 6400, with a normal differential count. The following chemical findings were noted: nonprotein nitrogen 150 mg., blood urea nitrogen 110 mg., blood sugar 96 mg. and serum protein 7.3 gm. (albumin 5.3 gm. and globulin 2.0 gm.) per 100 cc.; and serum chloride 95.4 milliequiv., the carbon dioxide combining power 21.2 millimoles, potassium 8.6 milliequiv., calcium 4.0 milliequiv., and phosphorus 3.6 millimoles per liter.

Radiographic examination showed the heart to be small and the lungs clear. The long bones appeared normal, but a minimal amount of calcification in the vessels of the lower legs and feet was noted. The kidneys were visualized on a flat plate of the abdomen and appeared small. The electrocardiogram was normal. Various tests of renal function were performed in an effort to elucidate further the nature of the underlying pathologic process. All these tests indicated a high degree of renal failure. The urea clearance was approximately 4 per cent of normal. A phenolsulfonphthalein test showed a total excretion of 9 per cent in 2 hours. The endogenous creatinine clearance was likewise greatly reduced (5.3 cc. per minute per square meter of surface area), and the tubular reabsorption (T_m) of glucose was also markedly impaired. The patient was discharged on May 28. At that time she was taking 12 gm. of supplementary sodium chloride and 6 gm. of sodium bicarbonate daily.

During the remainder of the year, the patient was followed in the Out-Patient Department of the Buffalo General Hospital. She remained moderately well and was able to lead a fairly active life, although occasional bouts of morning nausea and emesis continued to occur. During this period she continued to receive large doses of supplementary sodium chloride medication, which were necessary to allay nausea and to prevent a gradual rise in the blood nonprotein nitrogen level. As time went on, the quantity of sodium chloride solution that induced edema and convulsions became appreciably smaller, so that it became increasingly difficult to maintain the supplementary sodium chloride intake at a level that would alleviate nausea and keep the blood nonprotein nitrogen level from rising.

In January, 1942, the blood pressure had increased to 158/96. The blood urea nitrogen was 130 mg. per 100 cc., the serum chloride 116 milliequiv., the calcium 3.7 milliequiv., the phosphorus 3.0 millimoles and the carbon dioxide combining power 18.5 millimoles per liter, and the total protein

was 23.6 Bodansky units per 100 cc.

A few weeks later the patient complained of some diminution of visual acuity. Marked edema and punctate hemorrhages were noted in both retinas. The blood pressure had increased to 160/120. The heart was definitely enlarged, and ankle edema was present. Despite a reduction in the dosage of sodium chloride, the edema continued to increase and involved the face and abdominal wall as well as the legs and ankles. The patient was readmitted to the Buffalo General Hospital because of these findings. Despite all measures, her course progressed gradually downhill. Nausea and emesis were more frequent. On March 29, generalized convulsions began. At that time the blood pressure was 180/140, the blood urea nitrogen 144 mg. per 100 cc., and the serum chloride 100.5 milliequiv., the calcium 2.7 milliequiv. and the phosphorus 3.9 millimoles per liter. Following the convulsions, crepitus and swelling were noted over both clavicles. The presence of fractures was confirmed radiographically. Despite the administration of sedatives in large dosage, severe generalized convulsions recurred each day until April 4, when the patient's temperature rose to 107°F. and she expired.

Autopsy (Dr. Kornell Terplan). The body was that of a 154-cm.-long young woman. The entire integument showed a peculiar yellowish-gray coloring. There was distinct edema of the labia majora. The extremities showed slight edema, especially around the ankles. There was also slight edema of both upper arms. The breasts were extremely small and contained little parenchyma. The fat tissue of the breast showed distinct edema. The lower lip was edematous and slightly cyanotic. The teeth were in good condition, as inspected from without, and the gingiva was slightly bluish. The hair was light blond and fairly abundant. The pupils were 5.6 mm. in diameter.

The kidneys appeared markedly shrunken. The right kidney weighed 60 gm. and measured 9 by 3.5 by 3 cm.; the left kidney weighed 42 gm. and measured 7.5 by 3.5 by 2 cm. The capsules were unusually firmly adherent to the cortex. The capsule of the right kidney appeared somewhat thicker than that of the left. On the cut surface, a completely obscured picture was seen. The normal markings had disappeared. The cortex and medulla practically blended into one another, but even so it was apparent that the cortex was markedly atrophic, averaging between 1 and 2.5 mm. in thickness. The color of the cut surface was yellowish pink. No hemorrhages were visible grossly. After the capsule had been removed with great difficulty, the surface had a fairly regular, fine granular appearance, and here and there somewhat yellowish areas were noted near the surface. A few lentil-sized cysts and one hazelnut-sized cyst were present in the right kidney. The left kidney showed exactly the same picture. The fat tissue in the hilus of the kidney appeared relatively increased in amount. The kidney pelvis on each side was of corresponding dimensions. In the right pelvis, there were recent hemorrhages in the mucosa. The gross picture of the kidney was that of diffuse uniform shrinkage corresponding most closely to the late stages of contraction seen in diffuse glomerulonephritis. The branches of the renal arteries were not noticeable, and on section were apparently not thickened or stiffened. The right kidney was duplex, with two renal arteries, which were of normal caliber.

The adrenal glands were of normal size and weighed 7.5 and 8.5 gm. There was considerable lipid in the cortex. In one gland there were recent capillary hemorrhages in the medulla.

The heart weighed 270 gm. and showed distinct hypertrophy of the left ventricle, which measured 2 cm. in thickness near the bases. The right ventricle measured 5 mm. in the pulmonary conus. The trabeculae of the right side of the heart were fairly prominent. The endocardium in the left atrium showed moderate fibrosis. About 50 cc. of fluid was present in the pericardial sac. The thoracic duct was not remarkable. The foramen ovale was closed. The mitral ostium measured 8.5 cm. in circumference. The aortic valve measured 6 cm. in circumference, the pulmonary valve, 6.5 cm., and the tricuspid, 11 cm. The myocardium was slightly yellowish gray, apparently owing to a slight degree of anemia.

Both lungs showed moderate passive hyperemia and edema. There were fairly diffuse suffusions in the visceral pleura. The parenchyma in both lobes was decidedly consolidated

and dark bluish red. The trachea and bronchi showed marked hyperemia and capillary hemorrhages in the mucosa. The tracheobronchial lymph nodes were small and anthracotic. About 100 cc. of slightly bloody fluid was present in each pleural cavity. Both lower lobes showed superficial atelectasis, especially at the posterior aspects. The thyroid gland was of normal size. The cervical lymph nodes appeared moderately hyperemic. Three parathyroid glands were identified, one of them being slightly larger than normal. The larynx was not remarkable. The thymus gland was present but was considerably reduced in size.

The liver was normal in size and showed distinct passive congestion, edema and slight fatty changes of the peripheral portions. The bile ducts and gall bladder were not remarkable. The gall bladder was thin walled and not edematous and contained yellowish bile. The stomach showed a few coffee-groundlike flecks but no recent hemorrhages. The spleen was of normal size and contained a lentil-sized phlebotomy. The pancreas was not remarkable. The entire small intestine showed a peculiar greenish-black discoloration of the mucosa and contained somewhat digested semifluid matter. No hemorrhages were seen grossly. The mesenteric lymph nodes were small, and the colon showed a few petechial hemorrhages near the cecum. There was considerable pseudomelanosis throughout the mucosa of the small intestine. The thoracic and abdominal aorta were not remarkable.

The ribs were thin and cut easily. The cortex appeared somewhat atrophic. The bone marrow was distinctly reduced, and that in the vertebral bodies appeared somewhat anemic.

A variety of sections of the kidneys taken in vertical and frontal planes through the cortex and medulla showed the same picture of marked contraction, with almost all the glomeruli completely or almost completely hyalinized. Considerable hyalinization atrophy of many tubules with practically complete obliteration of their lumens was also noted. The few glomeruli still present were hypertrophic. They showed synchias to the capsule and, here and there, glandlike proliferation of the capsule epithelium. There were rare crescents, but these were for the most part hyalinized. A few glomeruli showed recent dilatation of capillaries, some of them with a considerable accumulation of leukocytes. Some had older hyaline and leukocytic exudate in the capsular space in the process of organization. A few recent capillary thrombi consisting mostly of fibrin and red blood cells were noted. The proximal convolutions were for the most part distended. They showed considerable epithelial desquamation and some fatty droplets. Here and there, erythrocytic, granular and a few small leukocytic casts were noted. The interstitial tissue showed dense infiltration with lymphocytes. The capsule was markedly thickened, infiltrated by lymphocytes and firmly adherent to the kidney. The branches of the renal artery showed only slight thickening of the intima. There was distinct thickening of arteries and arterioles only in the entirely fibrotic areas. In the remainder of the kidney the walls of the small arteries and arterioles were not remarkable. The entire picture corresponded to diffuse glomerulonephritis in the final state, with considerable fibrotic atrophy but still with marked degenerative changes in the somewhat hypertrophic proximal convolutions.

In the parathyroid glands, simple hyperplasia and marked hyperemia were observed. All the cells were so-called "water-clear" cells. Distinct edema was present in the capsules. All sections showed extensive ectasia of capillaries. One parathyroid gland contained a few minute follicles filled with colloid.

The clinical course of these patients is summarized in Tables 1 and 2. The onset of the disease, the clinical and laboratory findings, the response to therapy and the subsequent course of the disease were closely similar in both cases. Both patients were young adults (twenty-one years of age) on admission. The past history in both cases revealed little of significance except long-standing nocturia. There was no history of previous renal disease. The absence of abnormal skin or mucous-membrane pigmentation and the spontaneous hypoglycemia

were noteworthy. Routine urinalysis revealed only a slight trace of albumin. No formed elements were present in the urine sediment. Chemical examination of the blood revealed a striking reduction in the serum chloride level and an unusually high nonprotein nitrogen level. The hypotension, the small size of the heart, the absence of vascular changes in the retinal vessels and the essentially normal urine, however, favored a diagnosis of Addison's disease rather than that of uremia secondary to chronic nephritis.

Administration of adrenocortical hormone parenterally, sodium chloride solution intravenously and transfusion was followed by dramatic improvement in both patients. The blood pressure rose to normal levels within twelve hours, and nausea and vomiting ceased. Administration of sodium chloride solution and adrenocortical hormone was continued each day; despite the alleviation of symptoms and the restoration of normal blood pressure and serum chloride levels following this therapy, it was noted that the blood urea nitrogen failed to return to normal. Furthermore, phenolsulfonphthalein excretion was found to be reduced to less than 10 per cent of dye in two hours. These findings, although indicative of high-grade renal failure, did not eliminate the possibility of coexistent adrenal failure. Because of the critical condition of these patients, it was not considered justifiable to discontinue adrenocortical hormone therapy. It was found that both patients were able to tolerate 12 to 15 gm. of sodium chloride and 5 to 6 gm. of sodium bicarbonate daily without developing edema or hypertension, and that on this regimen the serum sodium and chloride concentrations were maintained at normal levels, the blood urea nitrogen level was reduced from 120 to 70 mg. per 100 cc., and both patients were able to lead a life of normal activity. Subsequently, carefully controlled studies revealed that the administration of desoxycorticosterone acetate (synthetic adrenocortical hormone) in large amounts was ineffective in maintaining sodium and chloride balance.

In Case 2, the patient discontinued sodium chloride administration following her initial discharge from the hospital. During the next two months weakness, nausea and vomiting recurred. These changes were associated with a fall in the blood pressure and the serum chloride level (to 71.2 milliequiv. per liter) and a rise in the blood urea nitrogen level (to 264 mg. per 100 cc.). Restitution of supplementary sodium chloride therapy was followed by a prompt remission in symptoms and marked improvement in blood pressure and blood chemistry.

Extensive renal-function tests were performed on both patients in an effort to determine whether the renal lesion primarily represented extreme reduction in all functional elements of the kidney or a specific defect in tubular reabsorption of sodium and

chloride. For details of these tests the reader is referred to the protocols. All tests performed indicated an extreme reduction in functioning renal mass. The degree of renal failure was so great that a valid comparison of the possible differences between glomerular filtration and tubular reabsorption could not be made.

In addition to renal-function tests, experiments were carried out to determine the effect of the ad-

The most striking feature presented by these patients was their ability to tolerate large quantities of sodium chloride (10 to 15 gm. daily) and sodium bicarbonate (4 to 6 gm. daily) without the development of edema and hypertension, in the presence of high-grade renal insufficiency. This phenomenon persisted until one to two months prior to death. It appeared that the ability of the kidneys to reabsorb sodium chloride in excess of

ministration of hormones whose action is known to be primarily or largely on the renal tubules. The inability of desoxycorticosterone acetate, parathormone and pituitrin treatment to affect the renal excretion of sodium chloride, phosphorus and water, respectively, is demonstrated in Figures 2, 3, 4 and 5. Administration of 20 mg. of desoxycorticosterone acetate daily for six days produced no significant change in the plasma volume or electrolyte balance

water was greatly impaired in both patients, and that the administration of large doses of supplementary sodium chloride was therefore necessary for the maintenance of an adequate plasma volume. Such treatment presented further increase in the level of blood urea nitrogen.

Both patients showed decidedly elevated serum phosphorus levels on all examinations. The serum calcium levels, however, were normal in one pa-

*Intravenous therapy consisting of glucose, sodium chloride and sodium lactate solutions.

(Figs. 2 and 3), whereas in normal subjects a striking increase in plasma volume and retention of sodium and chloride was encountered following the administration of 10 mg. of desoxycorticosterone daily.⁶ Administration of 200 units of parathormone (Fig. 4) failed to evoke the phosphorus diuresis induced by this hormone in normal subjects.⁷ Administration of pitressin (0.25 cc. every four hours) failed to effect a reduction in urine volume (Fig. 5). It is evident from these findings that failure to reabsorb sodium and chloride was not a specific metabolic defect on the part of the renal tubules of these patients. Glycosuria was not observed at any time.

tient (Case 1) and definitely below normal in the other (Case 2). It is of interest that latent tetany was usually present in the latter but less frequently so in the former. Involuntary muscular twitchings on the other hand, were seldom observed in Case 2 but were prominent in Case 1.

In Case 1, the patient was maintained in relatively good clinical condition for a period of nearly four years, and in Case 2 for slightly over two years, by the administration of large doses of supplementary sodium chloride and sodium bicarbonate. The terminal course in the two patients was similar. In each case it was noted that it gradually became increasingly difficult to maintain the sodium

chloride intake at a level that would prevent a rise in the blood urea nitrogen level and alleviate nausea and vomiting and yet not lead to hypertension and edema. At the same time, definite vascular changes began to appear in the vessels of the ocular fundi. Terminally, both patients lost ability to tolerate large doses of sodium chloride and developed edema, moderate hypertension and increasing nitrogen retention. The clinical picture changed considerably, so that at death it was perfectly consistent with the usual findings in long-standing chronic nephritis. The immediate cause of death was cardiac failure in Case 1, and uremic convulsions in Case 2.

DISCUSSION

It is our belief that the clinical syndrome that has been described is probably not associated with a typical pathologic lesion in the kidney, but rather occurs late in the course of insidious, slow but progressive renal disease. The slow rate at which the disease progresses and the absence of involvement of all nephrons at any one time permit considerable adaptation to fairly high-grade renal insufficiency. There result extensive scarring, hypertrophy of remaining glomeruli and dilatation of tubules. Under these circumstances the nice balance that normally exists between the quantity of sodium and chloride filtered through the glomeruli and reabsorbed by the tubules is disturbed to the extent that a small excess of sodium chloride is lost daily; ultimately this results in severe depletion of extracellular fluid volume, hemoconcentration and finally increasing renal failure. Increased water intake, without sodium chloride, accentuates the deficiency by increasing urine volume and hence sodium chloride loss.⁸ Terminally, with loss or impairment of the few remaining nephrons, the kidney is further limited in its function and both salt and water are retained, resulting in edema, hypertension and cardiac failure. It is our impression that ordinarily few patients live long enough in this precarious balance to reach the stage of severe dehydration and circulatory collapse. A moderate grade of sodium chloride depletion is not infrequently observed in patients with chronic nephritis, particularly when renal impairment is due to healed pyelonephritis, hydronephrosis or vascular nephritis (Peters⁵). It is possible to rehabilitate a number of these patients for periods of months to years by the careful administration of supplementary sodium chloride (1 to 5 gm. daily) and sodium bicarbonate (1 to 5 gm. daily) in conjunction with a large fluid intake (2500 to 4000 cc. daily). The administration of water alone, if it gives rise to a diuresis, may result rather rapidly in sodium and chloride depletion and hence ultimately reduce the volume of extracellular fluid and blood plasma and induce further renal insufficiency.⁸ The sodium chloride and sodium bicarbonate must be administered cautiously, in small doses and with due regard for the state of the circulation. Only those patients

with adequate cardiac reserve can derive benefit from increasing plasma volume and hence glomerular filtration with sodium chloride and sodium bicarbonate administration. Impending heart failure and excessive hypertension are contraindications to supplementary sodium chloride therapy, even in uremia.

Throughout the present paper merely the level of blood urea nitrogen has been discussed. This has not been done with the idea that the elevated blood urea is necessarily responsible for the clinical symptoms observed in uremia, but rather because in most cases the blood urea level parallels the clinical state.

SUMMARY AND CONCLUSIONS

A syndrome characterized by excessive loss of sodium, chloride and water, resulting in collapse and associated with renal disease rather than adrenal disease, is described.

Adrenocortical hormone is of no value in correcting the mineral depletion of these patients, since the renal tubular cell on which the hormone normally exerts its effect is unable to respond to additional hormone.

At present there does not appear to be a specific pathologic change responsible for excessive sodium and chloride loss other than widespread renal damage, associated with extensive scarring, a few remaining hypertrophied glomeruli and dilated tubules. Less severe loss of sodium and chloride is not infrequently observed in patients with chronic nephritis, and striking benefit may follow the judicious use of small quantities of supplementary sodium chloride and sodium bicarbonate under these circumstances.

For convenience and for its therapeutic implication, patients with chronic renal disease presenting evident signs and symptoms of sodium and chloride depletion may be said to be suffering from "salt-losing nephritis."

We are indebted to Drs. Richard A. Kern and Francis D. W. Lukens, of the University of Philadelphia, for their kindness in referring Case 1, and to Drs. Clayton W. Greene and Abraham H. Aaron, of the Buffalo General Hospital, for referring Case 2.

THE PROBLEM OF TUBERCULOSIS CONTROL*

JOHN A. FOLEY, M.D.,† AND JOHN B. ANDOSCA, M.D.‡

BOSTON

THE tuberculosis-control problem must be considered as the all-important factor if there is to be a reduction in the mortality and morbidity rate from pulmonary tuberculosis. One is told time and again that pulmonary tuberculosis is becoming a disease of the past and that it is only a matter of several years before it will be entirely eradicated. This is certainly a false notion. To be sure, the death rate in the United States has dropped from 201 per 100,000 in 1900 to 43 in 1940, but it must be remembered that this disease is still the leading cause of death between the ages of twenty and forty. The public is not aware of the magnitude of the present tuberculosis problem. This apparent indifference regarding tuberculosis is shown by the man in the street, who believes, in the absence of tuberculosis in his family, that the problem is non-existent.

It is apparent from a review of the death rate by occupation, age and sex that the largest numbers of

cases returned to society is small. In other words at present these huge sums of money are being spent yearly for the care and treatment of patients whose disease in 90 per cent of the cases is advanced. It would be a sound investment if more funds could be available for the maintenance of a sound and efficient tuberculosis-control program. By such a program the number of minimal cases would be definitely increased, and at the same time there would be a corresponding decrease in advanced cases.

At the Boston Sanatorium, the number of minimal cases admitted is certainly small (Table 1). It has also been noted that the female patients admitted fall into a lower age group than do the male patients. As would be expected, the age at death in the male patients is higher than that in the female patients (Fig. 1).

Although health departments are usually charged with the responsibility of city tuberculosis control

tuberculosis patients are to be found among the underprivileged and low-salaried groups. The huge economic and financial burden of the disease can easily be realized when the cost of long hospitalization is taken into consideration. The taxpayer supports this huge bill, and it is only a matter of time before he will ask for an accounting of these expenditures. That the tuberculosis sanatorium has contributed to the decline in tuberculosis cannot be denied. This contribution can be attributed more to the segregation of positive-sputum cases than to the number of arrested cases. The tuberculosis sanatorium could not possibly justify the expenditure of millions of dollars of the taxpayers' money on the basis of returns to the community in the form of arrested cases.

When it is considered that 90 per cent of the patients admitted to the sanatoriums have advanced disease, it is no wonder that the number of arrested

the sanatorium by virtue of its personnel and equipment should assume a place in the control program. The health department and the sanatorium should work as a single team, hand in hand, to assure success of any tuberculosis-control program. The City of Boston is fortunate in having an efficient health department that is properly and scientifically equipped and conducted. Through its able physicians and public-health nurses, together with its practicing physicians, it is safe to predict that there will be an increase in the number of minimal cases. The participation of the practicing physician is extremely important to a chest-clinic program, especially in the early notification of all cases of pulmonary tuberculosis. In this regard, it should be pointed out that in 1942 there were 388 deaths from pulmonary tuberculosis in Boston, yet only 209 of these occurred in the Boston Sanatorium. The remaining 179 patients must have died either in one of the general hospitals or at home. It is certain that the number that died in general hospitals is very small. It may be added that of the 209 deaths in the sanatorium in 1942, 57 per cent occurred within six months after the patients' admission (Table 2).

ificate dated within one or two days of each other. It is obvious that there is an urgent need for more

sanatorium against advice. A patient of this type is a source of danger not only to himself but also to his family and the community. Many of these patients go to and from the sanatorium at will, with the result that there has been a definite increase in readmissions (Table 4). The State legislators should look into this all-important problem in dealing with the unco-operative tuberculosis patient. Health laws should be strictly enforced in segregating this type of patient.

At the Boston Sanatorium during the last six

progressive, energetic case finding and early notification.

It is important to note that the number of patients discharged as apparently arrested, arrested or

years there has been an increase in the number of patients admitted, treated and discharged, whereas the average stay of the patient has been reduced (Table 4).

A considerable sum of money should be allotted in educating the public in the problem of tuberculosis.

The public is made somewhat tuberculosis-conscious by the sale of Christmas Seal stamps. The local medical societies should bring the tuberculosis

problem before the public even if it entails employing the radio and cinema.

All high-school children should be given the Mantoux test, and roentgenograms should be taken of all those with a positive reaction. Motorized x-ray field units, each accompanied by a trained roentgenologist and a technician, should be sent into those parts of the city from which most of the cases of tuberculosis come. The Army has aptly shown what can be done by mass x-ray examination. All inductees are examined by means of the 4-by-5-inch photoroentgenogram. It is said that about 1 per cent of all the inductees thus examined were found to have pulmonary tuberculosis. Of these, 90 per cent were found to be in the minimal stage of the disease, and approximately 10 per cent of the cases were classified as advanced. This figure corresponds closely, in reverse ratio, to the minimal and advanced cases admitted to this sanatorium. Many of the larger industrial firms are employing mass x-ray examination of their employees, with profitable results.

A geographic study of the entire city should be undertaken, for it can safely be said that most of the patients in the sanatorium come from certain sections, such as the crowded districts in Charlestown, East Boston, the South End and the North End.

Food handlers should be more carefully checked. It is surprising to see the number of patients admitted to the sanatorium who have been employed as cooks and waitresses.

In addition to the early diagnosis and treatment of pulmonary tuberculosis, it is important to secure the education and rehabilitation of the patient so that he may resume his rightful place in society. This education should be begun as soon as he is admitted to the sanatorium. The adjustment of the patient to his new environment and the solution of his family and economic problems are essential for ensuring a speedy and safe recovery.

Physicians and health units must be taught that post-sanatorium care is just as important as sanatorium care. There is no doubt that the patient will find himself back in the sanatorium unless post-sanatorium care is carefully carried out. It is the duty and obligation of the community to see to it that the patient and his family are well provided for. By so doing the community will realize a profitable return on the investment that has been made.

* * *

In summary, even if it is not possible at present to eradicate pulmonary tuberculosis, owing to its multiple and complex aspects, at least a well-managed and efficient program of tuberculosis control can and should be employed. This will surely bring about a definite reduction in the economic burden, mortality and morbidity rate resulting from pulmonary tuberculosis.

We are indebted to the W.P.A. Hospital Project 22206 for the preparation of Figure 1.

MEDICAL PROGRESS

PIGMENTATION OF THE SKIN*

HAROLD JEGHERS, M.D.†

BOSTON

THE color of the skin of patients is often of distinct diagnostic value. This is true not only for skin disease but also for a wide variety of systemic disorders likely to be encountered in the everyday practice of medicine. Standard textbooks on dermatology offer ready reference for orientation on the primary dermatologic diseases accompanied or followed by pigmentary changes in the skin. By contrast, information relative to the color of the skin in systemic diseases is widely scattered throughout the literature and is often difficult to locate without an extended search. Considerable advance

has been made in this field. It is the purpose of this progress report to present a summary and a key to the literature most likely to be available to the average physician. Wherever possible, attention is also called to typical photographs and color plates contained in these articles. Material for this review has been collected over the last eight years as patients presenting almost all diseases to be discussed were encountered at teaching exercises in the Medical Out Patient Department and on the wards of the Evans Memorial and the Boston City Hospital. During this time information relative to this subject was obtained from the literature, by correspondence or conversation with a number of physicians interested in these diseases and by personal observation of patients.

*From the Evans Memorial, Massachusetts Memorial Hospitals; the Fifth and Sixth (Boston University) Medical Services, Boston City Hospital; and the Department of Medicine, Boston University School of Medicine.

†Associate professor of medicine, Boston University School of Medicine; physician-in-chief, Fifth Medical Service, Boston City Hospital, and assistant physician, Clinical Staff, Evans Memorial, Massachusetts Memorial Hospitals.

NORMAL COLOR OF THE SKIN

Many attempts have been made to measure quantitatively and record the color of the skin in disease. A easy method is visual comparison of skin color with a series of color plaques. Rowntree and Brown¹ devised a universal skin tintometer, composed of nine separate color scales resembling somewhat the allqvist hemoglobin scale, that allowed evaluation of the skin color of anemia, jaundice, erythrosis, cyanosis and brown pigmentation. These color scales could be analyzed by the Munsell method of color measurement. The methods of Flagg² and Lewis³ (colored plate) for measurement of the degrees of cyanosis and the spinning color top method, widely used in anthropologic study of skin color of racial groups,⁴ are other examples. These methods have, however, not been generally used in clinical practice. Almost all physicians evaluate patient's skin color from visual impression. Knowledge of the causation of normal skin coloration and the pathogenesis of abnormal coloration will place this visual evaluation on a much more rational basis. More attention might be paid to this subject in the courses of applied physiology and physical diagnosis.

A brief summary of the histology of skin will aid in understanding the following discussion of skin pigmentations.⁵ From without inward the epidermal layer of the skin (epidermis) is composed of the stratum corneum (keratinized cells), the stratum acidum (clear acidophilic layer poorly defined except over the palms and soles), the stratum granulosum (a thin layer) and the stratum mucosum (the principal portion of the epidermis), which is attached to the dermis (corium) within and covered by the stratum granulosum without. Its inner surface is indented with papillary processes of the dermis that contain terminal capillary loops. The stratum mucosum is composed of a larger outer prickly-cell layer and a smaller basal layer of two or three rows of cells. Regularly distributed through the basal-layer portion are some clear cells (melanoblasts) that under certain stimuli enlarge, become dendritic and form melanin. Part of the melanin granules are carried outward and can be demonstrated in the outer layers of the skin. The superficial dermis contains cells (chromatophores) that can phagocytize but do not form melanin and that may also phagocytize other pigment complexes — metallic pigments, lipoids and so forth.

The most exact knowledge in this field is based on the spectrophotometric analysis of skin color, an approach pioneered in 1926 by Sheard and his associates.⁶⁻⁸ Sheard's work allowed skin color to be quantitatively evaluated in terms of relative luminosity, which tells how much of a standard source of light, such as sunlight, the given color is capable of reflecting; dominant wave length or hue, the latter an attribute of color that permits it to be classified as reddish, yellowish and so forth and depends on

wave length alone; and purity or saturation, which determines the degree of hue, establishing how vivid or distinct it is. Furthermore, specific absorption changes in spectrophotometric reflection curves enabled actual pigments to be identified. The role of melanin and hemoglobin was especially studied. Much valuable clinical information was obtained from the analysis of skin in disease by this method.⁶⁻⁸ Williams⁹ and Taussig and Williams¹⁰ successfully used an abridged spectrophotometer, which measured the reflected light through three successive filters, in studying the skin color of persons with skin cancer.

Using the Hardy recording spectrophotometer, developed in 1935, Edwards and Duntley¹¹ were able to study the quantitative distribution of pigments in the normal skin in a manner not possible with earlier instruments and also to identify pigments not previously noted. Briefly, this apparatus

records the reflectance of the intact living skin, giving an analysis by wave lengths over the entire visible spectrum, from the violet end at 400 millimicrons to the red end at 700 millimicrons. In the curve thus obtained, each pigment is identified by its characteristic absorption band. The amount of the pigment is indicated by the degree of absorption of the wave length of the band. Lowering of the reflectance at the particular wave length is therefore proportional to the amount of the pigment present.¹²

Analysis of normal subjects demonstrated five cutaneous pigments: melanin, a derived material described as melanoid, carotene, reduced hemoglobin and oxyhemoglobin.¹¹ The color of these pigments was subject to some modification by optical effects produced by the successive skin layers. This fundamental paper is well worth reading in the original.

Carotene

Edwards and Duntley¹¹ were able to demonstrate that carotene is important in all skin color and is not limited to patients with clinical carotenemia. They recognized the presence of carotene from its characteristic absorption in the blue region of the skin spectrum at 482 millimicrons. Carotene adds a strong yellow component to normal skin color. The normal quantitative bodily distribution of carotene is given in Figure 1, which is reproduced from their paper. It is at once apparent that the classic distribution of the yellow color in a severe case of clinically recognizable carotenemia is essentially an exaggeration of the physiologic normal distribution. Female subjects showed much more carotene throughout the skin than did male subjects. They also showed marked evidence of carotene deposition in the breast, abdomen and buttocks, regions of minimal carotene storage in the male. Carotene was not noted in the scrotum of male subjects, apparently because of complete replacement in this region of the subcutaneous fat by the dartos fibers.

Carotene is normally present not only in dermal and subcutaneous fat but also in the stratum corneum, and in amounts proportional to the thick-

ness of this epidermal layer, hence the prominence of the yellow color of the palms and soles in clinical carotenemia. Sebaceous matter contains a small quantity of carotene. Edwards and Duntley believe that carotene dissolved in the intercellular fluid is transmitted through the stratum mucosum to the stratum corneum. It is stored in the corneum because this layer, by virtue of its lipin content, has an affinity for the pigment, whereas the mucosum,

and very blond Whites whose ability to respond to light stimulus is minimal. The brunet always shows some secondarymentation (tanning). Some people, especially those with reddish hair and thin skin, manifest in a spotty form (freckles). Melanin is responsible for color effects in the skin varying through brown to black. The rare dominant yellow melanin lesion in children has been commented on,¹³ but a yellow hue, as in some types of freckles, is characteristic of the skin of women is generally poorer in melanin than that of men. The female areas of stratum corneum, such as the nape of the neck, the axilla and the axillas, however, show a higher melanin ratio than do the equivalent areas in the male. Androgens have a role in developing melanin.¹² Hamblen found the average daily androgenic excretion in the urine of true blonds to be distinctly lower than that of marked brunets.

It is generally agreed that the color of the skin is a faulty racial test unless correlated with other physical features of the body. Brunsting noted that although the percentage of melanin in the skin of Negroes was less than that of the skin of Japanese and Chinese than from that of the skin of the Chinese, the same hue prevailed in all. Edwards and Duntley's¹¹ study confirmed the idea that the color of the skin owes their characteristic colors only to the amount of melanin in the skin.

Fig. 1. Examination of results.

geographic study of the entire city should be undertaken, for it can safely be said that most patients in the sanatorium come from certain crowded districts in Charleston, South Carolina, and the North End. These areas are carefully checked. The number of patients admitted has been employed

made in this field. It is our report to present a summary of the literature most likely to be of interest to the physician. Wherever possible, we have led to typical photographs of the skin obtained in these articles. Melanin (reprinted from Edwards and Duntley, with permission of the authors and publisher)

presenting almost all the melanin encountered at teaching hospitals. Patient Department of the Memorial and the National Cancer Institute, these findings are found in Whites and other than those obtained from the Negroes, and the general distribution is identical in the dark-skinned races. The distribution of melanin pigment in the skin of patients with diseases of the skin is of interest in these diseases. The pigment contained in the skin of patients with diseases of the skin is of interest in these diseases.

Melanin is formed by melanoblasts, specialized cells in the basal layer of the epidermis at the junction of the epidermis and dermis. It occurs as microscopic granules in palisade cells of the basal layer of the epidermis, in decreasing amounts toward the stratum corneum, with but little melanin in the chromatophores of the corium except in the eyelids and axillas of some persons. Melanin is absent in albinos, present in the smallest amount in blonds, more noticeable in brunets and present in the largest amounts in the darker racial groups.^{11, 15}

Melanin is an endogenous body pigment whose mechanism of formation is not clearly understood but is in some respects controversial.¹⁵⁻²⁵ There is evidence that the metabolism of the amino acid tyrosine is in some way related to its formation. The metabolism of the amino acid phenylalanine is probably also related to pigment metabolism. Under certain circumstances phenylalanine is converted to tyrosine. In vitro studies show that tyrosinase acting with tyrosine forms a melanin-like pigment. Active melanin-producing melanoblasts are believed by many to contain an enzyme (dopa-oxydase) that causes a dark cytoplasmic reaction when a fresh section of skin tissue containing them is placed in a solution of dihydroxyphenylalanine (abbreviated to "Dopa"). A positive Dopa reaction is an indicator of the existence of the faculty of natural melanin production, however, not of the presence of melanin itself. Other epidermal cells and the melanophores of the corium are not Dopa-positive even though they may contain melanin. Controversy still continues concerning the exact meaning of the reaction; nevertheless, the test has much proved merit.^{15, 17} Melanoblasts, after having formed melanin, transport the pigment granules to the epithelial cells, and some are phagocytosed by the dermal melanophores. The sites of excretion of melanin appear to be from the skin by desquamation, through the intestinal tract and through the kidneys.¹⁸ Under certain conditions, especially with metastases from melanotic tumors a gross amount may occur in the urine (melanuria). The ingestion of melanin in foods and synthesis in the intestines may account for much of the pigments in melanosis coli.¹⁸

The chemical similarity of the amino acid tyrosine to the hormone of the adrenal medulla, epinephrine, to the thyroid hormone, thyroxine, and di-iodotyrosine, and of the amino acid phenylalanine to Dopa is worth keeping in mind. Dopa and tyrosinase have not been demonstrated in the human body, but some such similar mechanism for melanin formation is suspected. Melanin metabolism is undoubtedly influenced by pituitary, adrenal and thyroid activity, by the activity of a number of vitamins (A, C and parts of the B complex) and probably by the nervous system, since some writers believe that parasympathetic predominance stimu-

lates pigmentation formation, whereas sympathetic predominance inhibits it.^{22, 25} Many external factors acting on the skin, such as sunlight, artificial ultraviolet rays, x-rays, thorium rays, heat, mechanical irritation and chemical irritation, cause varying degrees of melanin pigmentation. A variable number of these factors, and probably others as yet unknown, may in a complex manner initiate melanin production in disease. It is apparent that analysis of the cause of increased melanin pigmentation in any single case is by no means an easy matter.

Melanoid

Disintegration of melanin particles gives rise to a diffuse pigment in the epidermis, first noted spectrophotometrically in the skin by Edwards and Duntley¹¹ and named melanoid. Melanoid has, on spectrophotometric analysis, a characteristic absorption, with its maximum slope resembling melanin but shifted from the ultraviolet to the visible violet, thus allowing it to be identified in the spectral reflection curve. They are inclined to believe that it tends to make the skin a yellow of higher purity than does any yellow that can be produced by melanin. The amount in any region depends on the degree of its formation and storage, its formation being related to the concentration of melanin in that particular locality, and its storage to the thickness of the epidermis; the latter is especially true where the stratum corneum (stored dead epithelium) is thick, but holds only to a negligible degree where the stratum mucosum (proliferating epithelium) is heavy and the corneum is thin. Melanoid storage is high in the soles and probably the palms, and minimal in the areas of heavy stratum mucosum in the buttocks, back, cheeks and neck. Furthermore, the turbidity of a thick stratum mucosum causes the optical effect of scattering and raises the blue end of the spectrum, masking the presence of melanoid. For this reason Edwards and Duntley were unable to chart accurately its quantitative distribution.

Oxyhemoglobin

The hemoglobin of blood is present as a varying mixture of oxyhemoglobin and reduced hemoglobin, both of which have such characteristic absorption bands and transmission peaks that recognition of their presence in a spectral reflection curve from the skin is relatively easy. Hemoglobin varies from 90 to 95 per cent oxyhemoglobin in arterial blood to approximately 50 per cent reduced hemoglobin in venous blood. Relative amounts of arterial and venous blood in the skin can thus be determined. Edwards and Duntley¹¹ found the oxyhemoglobin spectral pattern to be especially prominent in the regions of skin where there is a rich arterial supply and where, for the most part, dermal papillae with their contained capillaries are high. These areas are the red parts of the head and neck, the nipples

ness of this epidermal layer; hence the prominence of the yellow color of the palms and soles in clinical carotenemia. Sebaceous matter contains a small quantity of carotene. Edwards and Duntley believe that carotene dissolved in the intercellular fluid is transmitted through the stratum mucosum to the stratum corneum. It is stored in the corneum because this layer, by virtue of its lipin content, has an affinity for the pigment, whereas the mucosum,

FIGURE 1. *Distribution of Carotene* (reprinted from Edwards and Duntley,¹¹ with permission of the authors and publisher).

by virtue of a different chemical constitution, possesses no affinity for carotene. A heavy stratum mucosum without much overlying corneum effectively screens the underlying fat without contributing any carotene of its own. This, no doubt, is the explanation for the characteristic lack of yellow in the eyes and mouth of patients with marked carotenemia.

Melanin

Normal melanin pigmentation is of two types. Primary or native pigmentation is controlled by constitutional and racial factors and is responsible for the difference between a brunet and a blond White, the darkness of a Negro and also the regional characteristics exemplified in the normal increase of melanization of skin of the eyelids, nipples and scrotum.¹¹ Secondary or acquired pigmentation varies with exposure to sunlight and disappears after removal of this stimulus. The pattern of primary pigmentation has been difficult to determine accurately because of the varying degree of secondary pigmentation that all persons acquire. Nevertheless, fairly accurate estimates have been made. Utilizing their own and other available data, Edwards and Duntley have plotted the normal bodily distribution of melanin (Fig. 2). They emphasize that this primary pattern is best exemplified in members of the dark races, in whom the primary melanin layer protects from average sun exposure,

and very blond Whites whose ability to resist light stimulus is minimal. The average brunet always shows some secondary melanization (tanning). Some people, especially with reddish hair and thin skin, manifest melanization in a spotty form (freckles). Melanin is responsible for color effects in the skin varying from through brown to black. The rarity of a dominant yellow melanin lesion in clinical practice has been commented on,¹³ but a yellowish hue, as in some types of freckles, is common. Skin of women is generally poorer in melanin than that of men. The female areas of strong primary melanin, such as the nape of the neck, the axilla and the axillas, however, show a comparatively higher melanin ratio than do the equivalent areas in the male. Androgens have an important role in developing melanin.¹² Hamblen and Calkins found the average daily androgenic titer in the urine of true blonds to be distinctly lower than that of marked brunets.

It is generally agreed that the color of the skin is a faulty racial test unless correlated with physical features of the body. Brunsting and Sorenson noted that although the percentage of melanin luminosity was less from the skin of Negro, Indian, Japanese and Chinese than from that of white persons, the same hue prevailed in all. Edwards and Duntley's¹¹ study confirmed the idea that the characteristic colors of races owe their characteristic colors only to

FIGURE 2. *Distribution of Melanin* (reprinted from Edwards and Duntley,¹¹ with permission of the authors and publisher).

tions in the amount of the melanin and, they add, melanin is the pigment melanoid. No other pigment is found in Whites and is countered in these found in the general population of the pigmented races, and the general pattern of the pigment is identical in the groups. Indians and Negroes have a "redskin" arose from the custom of painting faces and not to the custom of painting the skin.⁷

Physicians are familiar with the red color produced by transilluminating living tissue (Fig. 5). They are, however, much less familiar with the importance of the blue color produced by the scattering phenomenon (Fig. 5).

The five skin pigments have in common a preponderant absorption in the blue end of the spectrum, so that were it not for the scattering phenomenon of the normal stratum mucosum, which tends to raise the blue end of the reflected spectrum, the skin would be much redder than it is.¹¹ Comment has already been made that the blue hue induced by the scattering phenomenon is offset in certain areas by the absorption of the melanoid. Variations in skin thickness, especially of the stratum mucosum,

the color is slate gray, and in unusual instances where pigment is deep in the dermis, the color is blue.¹² Other pigments present below the epidermis — silver, iron, carbon and so forth — may cause this phenomenon. It is thus apparent that the same pigment can cause variations in skin color depending not only on the amount present but on the level of the skin at which it is present.

Melanoblasts producing melanin in the corium account for the blue color of the blue nevus²⁶ and of Mongolian spots^{27, 28} (see colored plate²⁵). Diffuse melanin pigmentation in the corium may cause the subject to appear diffusely blue,^{29, 30} (see colored plate²⁹). Pigment deposited in the corium accounts for the blue color of the *taches bleues* from the

FIGURE 5. Diagrammatic Representation of the Process of Scattering (reprinted from Edwards and Duntley,¹¹ with permission of the authors and publisher).

cause this degree of scattering to vary likewise. The blue color of the larger superficial veins is dependent on this phenomenon. Hemoglobin is present in sufficient quantity to absorb all light striking it. Light cannot pass beyond the vessel into the subcutaneous tissue as it commonly does, so that the usual portion of the total skin reflection from the deeper tissues — predominant red (Fig. 5) — is thus absent. Skin reflection is entirely due to the predominantly blue light reflected from the turbid epidermis and turbid vein wall.

Melanin pigment in chromatophores in the corium if present in sufficient amount behaves in a similar manner, absorbing red rays and reflecting predominantly blue rays so that it appears as blue pigment beneath the skin. Other variations are possible. Becker and Obermayer¹⁵ summarize the color-producing properties of melanin in these words: "When a large amount of melanin is present in the epidermis, the color of the skin is brown, when predominantly in the dermal chromatophores (histiocytes) without too much epidermal pigment,

bites of *Pediculosis pubis*,³¹ the blue spots produced by hypodermic injections in drug addicts³²⁻³⁴ who use rusty needles or those with carbon particles from sterilizing in a flame (colored plate³⁴); the blue color produced by the black ink used by tattoo artists, the blue color of purpura when free blood is deep in the tissues,³⁵ probably the blue color of pinta in the pigmented phase and so forth.

Increased melanin in chromatophores probably explains some of the bluish color about the eyelids and in the axillas noted in certain persons. Bluish color caused by pigment in the hair shafts of the shaved male cheek is another physiologic example.¹¹ A shaved axilla no doubt may likewise show a bluish hue.

Anatomic Variations in Epidermis and Mucous Membranes

The normal epidermis varies in different areas of the body, not only in total thickness but in the relative thickness of each of its component layers. The influence of these normal anatomic variations on

the palms, the soles, the region of tuber ischii and the extensor surfaces of the joints. The quantitative bodily distribution of the predominant arterial blood pattern is given in Figure 3.

As is well known, oxyhemoglobin supplies a red component to skin color. Several factors that tend to suppress the oxyhemoglobin bands are present in the skin. The first of these is the increased reduced hemoglobin present in the venous limb of the capillary loop and in the subcapillary plexus with its strong venous blood component. Second, melanin, by its absorption across the spectrum, depresses the entire spectral reflection curve and thus tends to blunt the bands of oxyhemoglobin. This pigment, in proportion to its density, acts as a screen to prevent the superficial blood from attaining visibility. The difficulty of detecting erythema in a dark-skinned Negro is a representative clinical example of this phenomenon. Third, the turbidity of the stratum mucosum overlying the capillary loops adds the optical phenomenon of scattering and raises the blue end of the spectral curve. Brunsting and Sheard's⁸ study of the color of bloodless cadaver skin showed the major influence that blood in the superficial capillaries exerts on the color of the skin.

Reduced Hemoglobin

Parts of the body where the papillas are small or absent and where the subpapillary veins are more

prominent have no special predominance of either form of hemoglobin. Edwards and Duntley¹¹ denote these areas by the absence of dots (Figs. 3 and 4). In certain areas they noted a real predominance of reduced hemoglobin, probably due to dilated veins and a sluggish flow, as well as the factors minimizing the oxyhemoglobin color that have already been commented on. This phenomenon was

marked in the dorsum of the feet, and in the lower parts of the trunk, including the belly, scrotum, loins and buttocks, the last especially in the male. These areas are rich in superficial and comparatively dilated veins, possibly owing to the effect of gravity

FIGURE 4. Distribution of Venous Blood (reprinted from Edwards and Duntley,¹¹ with permission of the authors and publisher).

Figure 4 contains a diagram of the bodily distribution of these areas.

Reduced hemoglobin adds a blue component to all skin color and becomes predominantly noticeable in true cyanosis.

ANATOMIC AND OPTICAL MODIFIERS OF SKIN COLOR

The color of the skin produced by its five normal pigments is subject to modification by anatomic differences in the various parts of the body surface and the optical effect of the scattering phenomenon. These factors are responsible in part for all skin color, and especially in pathologic conditions in which they may form the mechanism for bizarre and decided variations from normal skin color.

Scattering Phenomenon

The significance of the phenomenon of scattering as a modifier of skin color has been especially emphasized by Edwards and Duntley.¹¹ Scattering is defined as the rearrangement of light as it passes through a turbid medium; the quantity of light transmitted contains a greater proportion of long wave lengths (red), whereas the light that is scattered to the sides or back to the surface of the medium contains a correspondingly large proportion of short wave lengths (blue). For example, the atmospheric air is a diffuse turbid medium and is responsible for the blueness of the sky at midday and its redness at sunset (Fig. 5). The relatively transparent stratum corneum shows only slight scattering, whereas the turbid stratum mucosum exhibits the phenomenon to a marked degree. All

uated in essentially the same areas in which it is normally most marked (Fig. 1). Lack of yellow color of the scleras immediately distinguishes it from jaundice (see colored plates⁴¹). Routine inspection of the palms of patients for yellow color easily suggests this diagnosis. It should be confirmed by the three-layer test of Greene and Blackford.⁴⁰

Jaundice

The aspects of jaundice relative to its influence on skin color appear to be poorly understood. The small amount of bilirubin normally present in the blood and tissues appears to play no detectable role in the causation of normal skin color. It was not detected spectrophotometrically by Edwards and Duntley⁴¹ in their study of the normal skin. The icterus index of blood must therefore increase well over its normal level of 4 to 6, probably well beyond 15 to 25, before it becomes clinically detectable. For the last five years the Fifth and Sixth Medical Services of the Boston City Hospital have performed an icterus index test, using the Wintrobe⁴² macroscopic examination of blood, routinely on every patient admitted. Experience has shown that jaundice was readily overlooked on the routine admission clinical examination even when the icterus index ranged over 50. Failure to examine patients with good illumination, preferably daylight, was chiefly responsible. It was the impression that tissue staining (clinically detectable) lagged behind plasma staining (measured by the icterus index) in the early phase of jaundice, the reverse being true as the improvement set in.

The color of the skin in jaundice is variable and has been described as varying from faint yellow through deep yellow, orange, saffron, yellowish green, green and even bronze or dark brown. It is a commonly held clinical belief that the tint of jaundice may be of some diagnostic significance. Some of these tints, as listed in Lichtman's⁴³ monograph, are orange or saffron in intrahepatic jaundice, greenish to bronze in obstructive jaundice, green in intrahepatic jaundice in the presence of liver necrosis and also in the receding stages of jaundice and olive green in cholangitis and cholangitic cirrhosis. The orange color has theoretically been attributed to bilirubin or the bilirubin pro-pigment, xanthorubin, and the green hue to biliverdin, the oxidation product of bilirubin.⁴³ Watson's⁴⁴ quantitative study of bile pigments has served to place these clinical impressions on a rational basis. Using the Evelyn photoelectric colorimeter he quantitatively measured the amount of biliverdin present in the serum of various types of jaundice. It was not found in pure retention jaundice. Perhaps the absence of biliverdin accounts for the lemon yellow of the retention jaundice of pernicious anemia. In regurgitation jaundice, whatever the cause, some biliverdin was noted regularly. Only in jaundice due to cancer

did it exceed 1.0 mg. per 100 cc. Watson's observations were in accord with the clinical impression that outspoken biliverdin jaundice is most frequently due to cancer of the biliary tract. A few marked exceptions were noted in parenchymal jaundice due to subacute or prolonged hepatitis or cirrhosis.

Jaundiced persons who look bronze or brown may have in addition melanin pigmentation. Scratching from pruritus and avitaminosis, both commonly present with long-persistent jaundice, are among the commonest causes for development of melanin pigmentation of the skin.

Wearn⁴⁵ has re-emphasized the diagnostic value of a sign but rarely referred to in the modern medical literature. It is described as a yellowish-blue or perhaps greenish color of the skin produced by a combination of the yellow of jaundice and the bluish purple of cyanosis. It is considered almost pathognomonic of an organic tricuspid lesion or a relative insufficiency of the valve. Wearn noted it in 17 of 24 cases. At times, jaundice and cyanosis occur together in other conditions, but their occurrence in other forms of heart disease is not frequent, and differentiation is not difficult.

Jaundice of prolonged duration during infancy may permanently stain with a green color the deciduous teeth forming during this time^{46, 47} (see colored plate⁴⁶).

Elastic tissue has a great affinity for bilirubin and is called "bilirubinophilic." This accounts for the ready pigmentation of the skin, sclera, blood vessels and cornea, which are rich in these fibers,⁴⁸ and its persistence after other body tissues have cleared. Distribution of these fibers probably accounts for the greater degree of pigmentation noted in the upper parts of the body.¹³

Meakins^{37, 38} and others³⁹ have commented on the absence of jaundice in edematous areas (see colored plate³⁷). This curious phenomenon explains the mechanism of the unilateral jaundice syndrome reported by Page,³⁹ who described it in 2 patients with cardiac failure and hemiplegia. Edema appeared only on the paralyzed side, whereas jaundice appeared on the other side. Jaundice in persons with one glass eye presents, on first glance only, the impression of looking at a person with unilateral jaundice.

A wheal formed by injecting histamine into jaundiced skin increases capillary permeability for bilirubin so that the wheal is yellower than the surrounding skin. The yellowish line bordered by two red lines formed by streaking the skin lightly (icterographia) is a similar phenomenon.⁴³ These procedures can be used as a simple skin test for latent or mild jaundice.⁴⁵⁻⁵⁰

Atabrine Pigmentation

The ability of the widely used antimalaria drug atabrine to produce frequently a yellowish pig-

skin color has already been commented on. For anatomical reasons, the color of mucous membrane is quite different from that of the body skin. Any anatomic change in the epidermis or mucous membrane may therefore act to modify its color. In general, thinner epidermis is more transparent and allows the blood in the dermal papillas and superficial dermis to shine through. Thicker epidermis is less transparent and looks yellower.³⁶

Variations in Capillary Blood Flow

Capillary blood flow through the skin is not constant but subject to many physiologic variations, causing the color produced by the contained blood pigments to vary accordingly. Brunsting and

The influence of edema on the distribution of pigment in the skin has been especially commented on.³⁷⁻³⁹

* * *

The term "pigmentation of the skin" as used in this review implies a change from normal of color of the skin, whether due to pigments present in the tissues or to those in the blood passing through the skin. The basic work of Sheard⁸ and Edwards and Duntley¹¹ shows clearly that color depends on both these factors. It appears to be much more rational and in keeping with physiologic principles always to think of skin color in this manner. Table 1 gives in tabular form a classification of abnormal skin color (pigmentation).

TABLE 1. *Classification of Skin Pigmentations* of General Medical Interest.*

Pigmentation due to other medicinal agents	
Unclassified pigmentations	

*As implied here, skin pigmentations may be localized or generalized, and are not primarily related or due to changes in the texture of the skin or to local skin lesions. The term "skin pigmentation" is used to designate changes in skin color due both to deposition of pigments in the skin and to pigments present in the blood.

Sheard⁸ give representative examples, such as vasodilatation following change to a warm environment, drinking of alcoholic beverages, local irritation from friction and an emotional disturbance with blushing, all making the skin redder, and vasoconstriction from environmental exposure to cold or the blanching caused by fear, giving a paler appearance. Pathologic processes can also cause profound change in skin color by varying the capillary blood flow.

Edema of Skin

Macerated skin is whiter than normal skin.¹⁵ Likewise, the presence of edema of the skin has a profound influence on skin color, as witness the pallor out of all proportion to the degree of anemia noted in patients with generalized edema of the nephrotic syndrome. Another example is the partial loss of pigmentation noted in some persons with Addison's disease due to the edema caused by desoxycorticosterone therapy and the rapid reappearance of pigmentation when they become dehydrated with the onset of an Addisonian crisis.

that is based on the above physiologic principles. This review primarily considers disorders of general medical interest and for the most part does not include dermatologic disorders. Throughout, attempts have been made wherever possible to crystallize working ideas and clinically useful axioms.

YELLOW PIGMENTATIONS OF THE SKIN

Carotenemia and Carotenoderma

The work of Edwards and Duntley¹¹ clearly shows that the pigment carotene contributes a yellow component to the color of the skin of all normal persons. This being so, carotenemia and carotenoderma of clinical significance are merely exaggerations of the normal minimal yellow color of serum and skin, respectively. This subject was viewed in detail last year in a progress report in this journal.⁴⁰ The yellow of carotenoderma is canary or lemon in hue, in contrast to the brown orange, saffron or green tint of jaundice (see color plates⁴¹). When clinically significant it is accom-

latous patients. Escamilla found carotenemia in consecutive cases of untreated myxedema, and similar findings were noted in 2 cases recently studied at the Boston City Hospital. Carotenemia has also been noted in Simmonds's disease⁵⁸ and in castrate and eunuchoid men.¹²

Krantz and Means⁶³ report 6 cases of myxedema manifesting areas of brownish pigmentation of the skin, more pronounced on exposed surfaces of the body. This pigmentation had appeared coincidentally with, or shortly after, the onset of symptoms of myxedema and cleared up promptly under thyroid administration. There was no pigmentation of the mouth. The description given in this paper is suggestive of chloasma areas of melanin pigmentation. The scarcity of such reports in the literature and the lack of similar descriptions in the current textbooks and monographs strongly suggest that a noticeable degree of generalized or localized melanin pigmentation of the skin in myxedema is not a frequent finding. It may possibly be explained as some fortuitous circumstance in the given case.

Pigmentation of Uremia

The skin in patients with long-standing renal failure is often of a peculiar pale, yellowish, yellowish-brown or buckwheat tint. Anemia undoubtedly accounts for the pallor. Becher⁶⁴ believes that, in renal insufficiency, chromogens of urine pigments are retained in the blood and become stored in the tissues and skin. The yellowish discoloration is most pronounced on the face and hands because under the influence of light the chromogens are changed into pigments as the result of oxidative processes. The light color of the urine in patients with uremia is believed to be due partly to retention of chromogens in the blood and in tissues and partly to an inability of the kidneys to oxidize these pro-pigments to pigments.⁶⁵

Boeck and Yater⁶⁶ noted carotenoderma in 10 per cent and carotenemia in 100 per cent of a group of kidney cases. It seems likely that carotenemia contributes to the pigmentation of patients with uremia. This has been attributed to poor urinary excretion of the carotenoid pigments, but the extent of urinary loss of carotene normally sustained is by no means agreed on.⁶⁶⁻⁶⁸

The brownish tint of the skin noted occasionally in patients with uremia is impressive. Whether any increase in skin melanin occurs is not known. Generalized pruritus is a common symptom in uremia. The resultant scratching irritates and mildly traumatizes the skin. Malnutrition is likewise frequent in uremic patients. These are among the known stimulants for an increase in melanin pigmentation of the skin, which may be additive to and blended with the underlying yellowish pigmentation of uremia. An excess of a hormone of the pars intermedia affecting pigmentation is men-

tioned as present in uremia.⁶⁹ What part, if any, this plays in the pigmentary syndrome of uremia of human beings is not known.

Dinitrophenol Pigmentation

Dinitrophenol is a pale-yellow crystalline powder used as an explosive, in the dye industry and for the preservation of timber. Only the 2-4 isomer has toxic properties. During 1915 and 1916 poisoning of workers in shell-filling factories in France was frequent. Workers showed yellow staining of the face, legs, forearms and especially the palms and soles. Hunter⁷⁰ has recently reviewed the clinical features of the mild and severe forms of systemic poisoning. By 1918 industrial precautions were so well developed that dinitrophenol was used with little or no poisoning resulting from its handling.

American physicians became familiar with 2-4-dinitrophenol in 1933, when because of its metabolic stimulating properties it was used for the treatment of obesity.⁷¹ For a time it was widely used for weight reduction, both by prescription and in numerous proprietary preparations. The many reports of toxic reactions from its use led to its general withdrawal as a therapeutic agent. Of interest here was the observation that dinitrophenol often discolors the scleras and even the skin, thus simulating the clinical appearance of jaundice.⁷² The discoloration is due to the drug in the plasma and body tissues. It varies from time to time and disappears gradually after ingestion of the drug is discontinued. Since it colors serum and plasma, it may give false high values for the blood icterus index. This can be avoided by determining the index on blood plasma that has been acidified.⁷²

Except in rare cases, dinitrophenol does not cause liver damage and jaundice.^{72, 73} Liver function is usually normal.^{74, 75} The yellow color is purely one of staining tissue and blood. If yellow pigmentation due to dinitrophenol is suspected, the diagnosis can be established on the basis of a history of using a remedy for weight reduction and determination of the icterus index with acidified plasma as compared to nonacidified plasma.

Staining Due to Substances of Industrial Origin

There are a number of chemicals used in certain industries that produce yellow staining of the skin in employees exposed to or handling them. An important one of these is tetryl, or trinitrophenyl-methylnitramine, a pale-yellow crystalline powder that is an important ingredient in explosives. Employees handling tetryl powder frequently develop a yellow staining of the hands in one to three days and of the face, neck, scalp and hair in one to three weeks.⁷⁶ This color deepens on exposure to sunlight and becomes more prominent during the summer.⁷⁵ In industry the terms "canary" and "tetryl blond" are frequently used to describe persons with

mentation of the skin is by now known to many physicians. The review by Schechter and Taylor⁵¹ dealing with atabrine pigmentation has served to emphasize the importance of this subject. This pigmentation may closely simulate jaundice and lead to diagnostic error. This is especially true if it persists for months and a different physician than the one who ordered the drug sees the patient some time after this medication was discontinued.

The skin pigmentation is noticeable within three to ten days of beginning oral therapy and may persist for a few weeks to as long as four months after discontinuance of the drug.^{51, 52} Parenteral administration of the soluble form of the drug does not eliminate the possibility of pigmentation.⁵¹

The pigmentation is diffuse and most prominent on the dorsum of the hands, arms and feet. It appears on the forehead and face and may form a golden ring around the mouth.⁵¹ Soni⁵² has emphasized that the pigmentation is usually most marked on the exposed parts of the body. It may also be accentuated in the interdigital skin folds and neck creases and under the breasts.⁵¹ No changes occur in the texture of the skin.⁵² The color has been variously described as lemon, greenish yellow, golden yellow and turmeric, but in any event a yellow component is clearly evident. A medical officer has described it as "a sickly greenish yellow."

Staining of the mucous membranes has not been emphasized in the printed reports and appears to be less reliable and noticeable than the skin color. Schechter and Taylor⁵¹ emphasize that contrary to the experience of others they have failed to notice any significant discoloration of the scleras, a point that is in accord with the extensive experience of two Army medical officers who discussed this subject with me. Further observations will no doubt settle this question. Martin, Cominole and Clark⁵³ noted yellowish discoloration of the scleras in experimental animals receiving toxic doses of atabrine (0.1 to 0.2 gm. per kilogram of body weight), but not when the dosage was reduced to 0.05 gm. Perhaps the same phenomenon occurs in human beings. If found consistently, the lack of significant scleral pigmentation would readily differentiate atabrine pigmentation and jaundice. Atabrine pigmentation can be distinguished from carotenemia by the deeper pigmentation of the dorsum of the hands in the former and of the palms and soles in the latter.⁵¹ Yellow staining of the skin from chemicals must naturally be eliminated. Quinine does not cause pigmentation.⁵² Plasmochin in toxic doses may cause cyanosis from methemoglobinemia.

Atabrine pigmentation appears to result from deposition of the dye in the skin rather than from a secondary metabolic disturbance or liver damage.⁵¹⁻⁵³ Hecht⁵⁴ demonstrated that the pigment found in animals was fluorescent, which suggested

that it was either atabrine or a breakdown product thereof. Atabrine does not cause liver damage except possibly when diminished glycogen reserve from malnutrition is present.⁵⁴ Ruge⁵⁵ has presented data indicating that chemical and clinical reactions characteristic of hepatic damage in acute malaria return to normal under atabrine therapy. Atabrine pigmentation, if prolonged, may be indicative of accumulation of the drug. Constipation, anemia and exhaustion from infectious disease are believed to augment the intensity and duration of the pigmentation.^{51, 52} The more marked accentuation of the pigmentation on the exposed parts of the body has suggested some influence of the rays of the sun.⁵²

Tests for hyperbilirubinemia are necessary in suspected concurrent jaundice and atabrine pigmentation. Schechter and Taylor⁵¹ have outlined a simple laboratory procedure that detects atabrine even if only 0.02 mg. is present in the urine. Hansen⁵⁶ has reported on the use of atabrine take for the purpose of simulating jaundice.

Pigmentation of Myxedema

Descriptive terms such as sallow yellow, yellowish pallor, old-ivory tint, waxy yellow and slight icteric have been commonly used to describe the color of the skin in myxedema.^{57, 58} A malar flush or "a light spot of pink high in the center of the cheeks,"⁵⁷ yellowish sallowness of the rest of the face and the presence of edematous, coarse-looking features constitute the characteristic facies of myxedema (see colored plate⁵⁹). The pallor component of the color is readily explained by the high incidence of anemia in this disorder.⁵⁸ The myxedematous condition of the skin probably also contributes to the pallor.

The yellow component of the skin color is of special interest. Rarely pernicious anemia coexists with myxedema.⁶⁰ Under this and perhaps other exceptional circumstances bilirubin pigment may produce a yellow skin pigmentation in myxedema. In the vast majority of cases, however, this is not the cause. The recent reports by Escamilla and Mandelbaum et al.⁶¹ confirm earlier observations⁶² that the yellowish color so frequently noted in myxedema is due to carotenemia, which may occur in this disease even when the amount of carotene in the diet is low. According to Escamilla, the conversion of carotene to vitamin A in the liver is hindered by the depressing effect of the lowered metabolism and tends to improve gradually under treatment with thyroid substance. It is believed by some that the thyroid hormone is antagonistic to vitamin A and governs the rate of its consumption. In hypothyroidism the vitamin A in the serum is normal or low, whereas the carotene is increased. Careful inspection of the palms for a yellow color and Greene and Blackford's three-layer test of the serum should be done routinely in all myxedema.

jaundiced patients. Escamilla found carotenemia in consecutive cases of untreated myxedema, and similar findings were noted in 2 cases recently studied at the Boston City Hospital. Carotenemia has also been noted in Simmonds's disease⁵⁸ and in castrate and eunuchoid men.¹²

Krantz and Means⁶³ report 6 cases of myxedema manifesting areas of brownish pigmentation of the skin, more pronounced on exposed surfaces of the body. This pigmentation had appeared coincidentally with, or shortly after, the onset of symptoms of myxedema and cleared up promptly under thyroid administration. There was no pigmentation about the mouth. The description given in this paper is suggestive of chloasma areas of melanin pigmentation. The scarcity of such reports in the literature and the lack of similar descriptions in the current textbooks and monographs strongly suggest that a noticeable degree of generalized or localized melanin pigmentation of the skin in myxedema is not a frequent finding. It may possibly be explained as some fortuitous circumstance in the given case.

Pigmentation of Uremia

The skin in patients with long-standing renal failure is often of a peculiar pale, yellowish, yellowish-brown or buckwheat tint. Anemia undoubtedly accounts for the pallor. Becher⁶⁴ believes that, in renal insufficiency, chromogens of urine pigments are retained in the blood and become stored in the tissues and skin. The yellowish discoloration is most pronounced on the face and hands because under the influence of light the chromogens are changed into pigments as the result of oxidative processes. The light color of the urine in patients with uremia is believed to be due partly to retention of chromogens in the blood and in tissues and partly to an inability of the kidneys to oxidize these pro-pigments to pigments.⁶⁵

Boeck and Yater⁶⁶ noted carotenoderma in 10 per cent and carotenemia in 100 per cent of a group of kidney cases. It seems likely that carotenemia contributes to the pigmentation of patients with uremia. This has been attributed to poor urinary excretion of the carotenoid pigments, but the extent of urinary loss of carotene normally sustained is by no means agreed on.⁶⁶⁻⁶⁸

The brownish tint of the skin noted occasionally in patients with uremia is impressive. Whether any increase in skin melanin occurs is not known. Generalized pruritus is a common symptom in uremia. The resultant scratching irritates and mildly traumatizes the skin. Malnutrition is likewise frequent in uremic patients. These are among the known stimulants for an increase in melanin pigmentation of the skin, which may be additive to and blended with the underlying yellowish pigmentation of uremia. An excess of a hormone of the pars intermedia affecting pigmentation is men-

tioned as present in uremia.⁶⁹ What part, if any, this plays in the pigmentary syndrome of uremia of human beings is not known.

Dinitrophenol Pigmentation

Dinitrophenol is a pale-yellow crystalline powder used as an explosive, in the dye industry and for the preservation of timber. Only the 2-4 isomer has toxic properties. During 1915 and 1916 poisoning of workers in shell-filling factories in France was frequent. Workers showed yellow staining of the face, legs, forearms and especially the palms and soles. Hunter⁷⁰ has recently reviewed the clinical features of the mild and severe forms of systemic poisoning. By 1918 industrial precautions were so well developed that dinitrophenol was used with little or no poisoning resulting from its handling.

American physicians became familiar with 2-4-dinitrophenol in 1933, when because of its metabolic stimulating properties it was used for the treatment of obesity.⁷¹ For a time it was widely used for weight reduction, both by prescription and in numerous proprietary preparations. The many reports of toxic reactions from its use led to its general withdrawal as a therapeutic agent. Of interest here was the observation that dinitrophenol often discolors the scleras and even the skin, thus simulating the clinical appearance of jaundice.⁷² The discoloration is due to the drug in the plasma and body tissues. It varies from time to time and disappears gradually after ingestion of the drug is discontinued. Since it colors serum and plasma, it may give false high values for the blood icterus index. This can be avoided by determining the index on blood plasma that has been acidified.⁷³

Except in rare cases, dinitrophenol does not cause liver damage and jaundice.^{72, 73} Liver function is usually normal.^{74, 75} The yellow color is purely one of staining tissue and blood. If yellow pigmentation due to dinitrophenol is suspected, the diagnosis can be established on the basis of a history of using a remedy for weight reduction and determination of the icterus index with acidified plasma as compared to nonacidified plasma.

Staining Due to Substances of Industrial Origin

There are a number of chemicals used in certain industries that produce yellow staining of the skin in employees exposed to or handling them. An important one of these is tetryl, or trinitrophenylmethylnitramine, a pale-yellow crystalline powder that is an important ingredient in explosives. Employees handling tetryl powder frequently develop a yellow staining of the hands in one to three days and of the face, neck, scalp and hair in one to three weeks.⁷⁶ This color deepens on exposure to sunlight and becomes more prominent during the summer.⁷⁵ In industry the terms "canary" and "tetryl blond" are frequently used to describe persons with

this yellow staining of the hair, scalp and face.⁷⁶ It is not necessarily indicative of impending dermatitis. Tetryl dermatitis generally occurs between the second and the third week of exposure and is characterized by a burning, itching, erythematous, edematous rash of the circumoral region of the face and the lateral surfaces of the neck, and less frequently of the arms. It is often stated that tetryl produces only these local manifestations. Witkowski et al.⁷⁶ stress that systemic symptoms, such as epistaxis, sneezing, nonproductive cough, chest pain, anemia, increased irritability and anorexia, may occur. The presence of yellow staining aids in evaluating patients with industrial exposure. The history of occupational exposure, staining of the hair, the lack of yellow scleras and the fact that tetryl does not cause jaundice enable the physician to recognize readily the significance of the yellow staining.

Other substances handled industrially likewise stain exposed skin surfaces yellow in a manner similar to tetryl. Picric acid,⁷⁷ trinitrotoluene (see colored plate⁷⁸), styphnate, nitric acid⁷⁷ and the German explosive, hexanitrodiphenylamine,⁷⁷ are among the more important ones. In sharp contrast to tetryl, some of these may cause liver damage and true jaundice. Jaundice occurring in an industrial "canary" can readily be overlooked.

PICRIC ACID PIGMENTATION

Simulated Jaundice

Judging from the literature appearing during World War I, simulated jaundice as a form of malingering was evidently not uncommon in some of the European armies.⁷⁹⁻⁸¹ As a medical curiosity it ranks with the use of egg albumin in the urine to simulate albuminuria and injections of turpentine and paraffin to produce artificial abscesses.⁸² Simulated jaundice was produced by the oral ingestion of 5 to 10 cgm. of picric acid three times a day in pill form.⁷⁹⁻⁸² Within one or two days the skin and scleras became pigmented yellow and on routine clinical inspection the patient could pass as having jaundice. Vomiting, abdominal pain, anorexia, nausea and diarrhea were often noted. The urine was more likely to be orange to red than to have the usual bile-stained appearance, but was sometimes normal in color. A yellow color is due to staining of the tissues by picric acid, or more likely to a breakdown product such as picramic acid. The stain sometimes persisted for several weeks. A similar syndrome has been reported from picric acid absorbed from ointment used to treat an open wound.⁷⁹ Numerous tests of the urine and blood were devised to detect the simulation of jaundice from ingestion of picric acid.^{79, 80, 82, 83} The practice entailed danger, since picric acid is toxic to the liver and true jaundice from liver damage could be grafted onto the picture of pseudojaundice.^{81, 84}

From the scarcity of reports in the current literature it appears that simulated jaundice has been encountered during World War II or possibly has not been reported. Hansen⁸⁵ reports a ca simulation of jaundice by the use of atabrine.

Local Discoloration of Abdominal Wall

Cullen,⁸⁵ in 1919, described the occurrence of discoloration resembling a bruise at the umbilical area of a woman with a ruptured ectopic pregnancy and utilized this sign to make the correct operative diagnosis. The diagnostic value of this sign was confirmed by Hellendall,⁸⁶ Novak⁸⁷ and many others.⁸⁸ Smith and Wright⁸⁸ reviewed the literature in detail in 1935 and concluded that this sign is a rare indication of intraperitoneal hemorrhage. In the foreign literature it is sometimes known as the Hofstätter-Cullen-Hellendall sign. Most frequently it is called Cullen's sign and is considered diagnostic of intraperitoneal hemorrhage.

Two phenomena appear to have been described under this sign.⁸⁹ One is the bluish discoloration noted when intraperitoneal blood is seen through the thin tissue of an umbilicus, a hernia, an incision and so forth. The production of the bluish color apparently involves the same optical phenomenon as described previously for the blue color of skin veins. The other condition is the discoloration of the subcutaneous tissues about the umbilicus, incisions, near the anterosuperior spine of the ilium and in the loins. The color resembles a bruise; it is bluish at first, then becoming bluish green and finally yellowish (see colored plates^{85, 87, 90}). The term "Cullen's sign" should be applied to the latter phenomenon.⁸⁸ The changing shades of color have been explained as due to oxidation of blood elements traveling in the lymphatics connecting the umbilicus or incisional area with the peritoneal cavity.

Grey-Turner⁹¹ recorded similar local areas of pigmentation in 2 patients with hemorrhagic pancreatitis, in one case about the umbilicus and the other in the loins. Direct action of hemorrhagic pancreatic juice escaping by way of retroperitoneal tissue may have produced the loin pigmentation (see illustration⁹¹). The term "Grey-Turner's sign" has been applied to this phenomenon especially by English writers. Its value for diagnosis of acute hemorrhagic pancreatitis has been amply confirmed.^{89, 92, 93} Fallis⁸⁹ reports that in one clinical case the correct preoperative diagnosis was made in 3 of 35 cases on the basis of the clinical phenomenon of localized discoloration of the abdominal wall. This sign in acute pancreatitis should not be confused with the cyanosis described by Halsted⁹⁴ and others,^{95, 96} which may take on a mottled pattern and be distributed irregularly over the surface of the abdomen and even the extremities. It is probably a manifestation of peripheral circulatory collapse.

Yellowish pigmentation about the umbilicus due to rupture of the common bile duct was described by Ransohoff.⁹⁶ Other causes of hemoperitoneum besides ruptured ectopic pregnancy may cause this phenomenon. There is some evidence that extra-peritoneal spread of blood is responsible for this sign. It has been reported as present without free intraperitoneal blood and often absent with gross hemoperitoneum.^{88, 89} This sign can be readily overlooked unless searched for carefully with good illumination.

Miscellaneous Pigmentations

Skin lesions characterized by both a yellow color and a recognizable local gross change in skin morphology should not be confused with the type of yellow pigmentation discussed in this review. A clear orientation in this field is given by Weidman¹³ in his review of the many nonxanthomatous skin conditions characterized by a yellow hue, and by Montgomery⁹⁷ and Thannhauser and Magendantz⁹⁸ in accounting for the many different types of xanthomatous skin lesions. In xanthomatosis, the entire surface of the skin is sometimes tinted a chamois or pale yellow.⁹⁹ The whole skin area in so-called "systematized amyloidosis" may be of a waxy coloration.¹⁰⁰ Hansen⁵⁶ has commented on the yellow skin color that may result from the use of santonin or acriflavin. The earlier literature has emphasized the yellowish discoloration of the palms noted in persons with typhoid fever and known as "Filipovitch's sign."⁹⁹

A peculiar type of jaundice has been described as being present in the septicemias due to gas-bacillus infections, especially in the post-abortive group. The skin color varies from brownish yellow to mahogany. This color has been attributed to the presence in the plasma of bilirubin, oxyhemoglobin, hematin and methemoglobin.¹⁰¹

BENJAMIN CASTLEMAN, M.D., *Acting Editor*

EDITH E. PARRIS, *Assistant Editor*

CASE 30291

PRESENTATION OF CASE

A forty-two-year-old teacher entered the hospital for study.

The patient had been in excellent health until four and a half months prior to entry, when he had an attack of chills, fever, cough, chest pain and rusty sputum. He spent five weeks in a hospital in another city, where he was given various sulfonamide derivatives without much benefit but finally recovered. Following discharge from the hospital he slowly gained 10 pounds. He had an occasional dry cough,

*On leave of absence.

but was getting along well until three weeks before admission, when a follow-up x-ray film of the chest taken by his physician showed a persistent lesion in the right upper lobe. He was then bronchoscoped in another city; a biopsy was said to have shown epidermoid carcinoma by one pathologist and squamous-cell metaplasia by another. There was no history of exposure to tuberculosis.

Physical examination showed a well-developed, well-nourished man in no distress. Examination was negative except for slight dullness over the right upper lobe, with increased tubular breathing below.

The blood pressure was 140 systolic, 85 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,680,000, with 14 gm. of hemoglobin. The white cell count was 9200. A blood Hinton test was negative. The urine was normal. The nonprotein nitrogen was 32.5 mg. per 100 cc.

X-ray examination of the chest (Fig. 1) showed partial collapse of the posterior medial segment of the right upper lobe. Within the area of collapse were several air-bearing areas, such as those seen in consolidation of the lung with an open bronchus. The right lower and middle lobes showed some

compensatory overexpansion. The right leaf of the diaphragm moved somewhat limitedly with respiration. The mediastinum was retracted to the right of the area of collapse. There were no evident hilar lymph nodes, pleural effusion or bone metastases. When compared with the films made elsewhere there

response of the fever or merely persistence of physical signs for four and a half months.

DR. BENJAMIN CASTLEMAN: They found a Type 2 pneumococcus in the sputum.

DR. BECKMAN: That is helpful because, of course, the presence of a Type 2 pneumococcus in the

FIGURE 1. *Roentgenogram of Chest*

seemed to have been some reventilation of the lung since the previous examination.

On the fourth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. WILLIAM BECKMAN: I find this case singularly lacking in details that I should like to have in order to make a definite diagnosis. It seems that there can be no doubt, with the initial symptoms four and a half months before admission of chills, fever, cough, chest pain and rusty sputum, that the patient had pneumonia of some sort. These are the characteristic features of pneumonia, and I do not believe anything else could produce that picture, although sometimes a pulmonary infarct may simulate it. I do not suppose that the details of the illness in the other hospital are available, but it would be interesting to know in just what way he did not respond to treatment—whether it was a lack of

sputum is uncommon unless it is producing disease. I suspect that it can occasionally inhabit the normal nasopharynx, but in general it indicates infection, which lends further proof to the idea that the patient had lobar pneumonia at the time of admission to the other hospital. Most likely he had a sulfonamide-fast organism or he would have responded better than he did, although we do not know the nature of the course in that hospital. Later, however, he gained 10 pounds to replace some of the weight that he had lost during that illness. Apparently he was in good health, except that the doctor thought he should have a check-up, following which he was advised to come here for study.

It seems to me that one can reason about this case in two ways. The first is that the lesion found at the time of the admission to this hospital was a sequela of the acute infection that he had had four and a half months before. The common complications of pneumonia are, of course, empyema and

CASE 30291

PRESENTATION OF CASE

A forty-two-year-old teacher entered the hospital for study.

The patient had been in excellent health until four and a half months prior to entry, when he had an attack of chills, fever, cough, chest pain and rusty sputum. He spent five weeks in a hospital in another city, where he was given various sulfonamide derivatives without much benefit but finally recovered. Following discharge from the hospital he slowly gained 10 pounds. He had an occasional dry cough,

but was getting along well until three weeks before admission, when a follow-up x-ray film of the chest taken by his physician showed a persistent lesion in the right upper lobe. He was then bronchoscoped in another city; a biopsy was said to have shown epidermoid carcinoma by one pathologist and squamous-cell metaplasia by another. There was no history of exposure to tuberculosis.

Physical examination showed a well-developed, well-nourished man in no distress. Examination was negative except for slight dullness over the right upper lobe, with increased tubular breathing but no rales.

The blood pressure was 140 systolic, 85 diastolic. The temperature, pulse and respirations were normal.

Examination of the blood showed a red-cell count of 4,680,000, with 14 gm. of hemoglobin. The white-cell count was 9200. A blood Hinton test was negative. The urine was normal. The nonprotein nitrogen was 32.5 mg. per 100 cc.

X-ray examination of the chest (Fig. 1) showed partial collapse of the posterior medial segment of the right upper lobe. Within the area of collapse were several air-bearing areas, such as those seen in consolidation of the lung with an open bronchus. The right lower and middle lobes showed some

*On leave of absence.

ight resemble this. I was particularly interested what he had to say about the cases of lobar pneumonia that clear up not by resolution but by organization.

There are a number of features that are consistent with this under the heading of subacute and chronic durative pneumonia. He says, for example, that, when resolution does not take place, but instead there is organization of the exudate, one gets a type of induration that tends to contract, as this had done. He says that it is commoner in cases of pneumonia that have not responded as they should and where the fever has persisted, which is the case here. I was rather intrigued with these areas that might have been cavities, since Dr. Lord speaks of dilatation of the bronchi or cavities in the lung, which may give the breathing an amphoric quality. I therefore mention organizing pneumonia as a possibility in this case. I think that the case hinges on which pathologist was right. One said that he had cancer, and the other that he did not. If he had cancer, he had cancer!

DR. SWEET: I am pleased that this case was discussed here. I had hoped that Dr. Castleman would also present another case, which is a running mate of this one, the patient having been observed continuously at this hospital for a period of five months. The diagnosis was the same in both cases, and in both cases were mystifying before operation. Of course one must remember that the patient whose case is discussed here today was sent to me with a diagnosis of carcinoma of the bronchus of the right upper lobe. He and his family had been so informed. He was an apprehensive person and very much worried. It is obvious to those of you who are familiar with carcinoma of the lung that the opportunities to remove small, and perhaps curable, lesions are few and far between. Because I know the man who did the bronchoscopy, I was confident that I could rely entirely on the accuracy of his observation and that we could not have done any better here. So I did not have another bronchoscopy performed. I did get the slides and went over them with Dr. Ronald C. Sniffen, who did not agree with the diagnosis of carcinoma. I therefore made a diagnosis of collapse of the right upper lobe due to obstruction of a process beyond where one could see it with the bronchoscope.

The most frequent cause of that picture, in my experience, is tuberculosis. In other words the usual cause of occlusion of bronchi in the upper lobe is tuberculosis. But I did not believe that this man had tuberculosis. I cannot tell you exactly why. One reason was that he did not have acid-fast organisms in the sputum, and as Dr. Holmes has said, the x-ray picture did not look like that of tuberculosis. I ended up by operating in the hope that I might be getting ahead of an early carcinoma that could not be seen through the bronchoscope. When I got in, there was complete collapse of the

right upper lobe, as the x-ray shows. The lobe was densely adherent and exceedingly difficult to get out. In that respect it was very much like the lungs found in many cases of tuberculosis. On the other hand there was difficulty of dissection around the hilus of the lung, which is unlike tuberculosis. I left the operating room still with the impression of tuberculosis, but I did not know whether it was.

CLINICAL DIAGNOSIS

Carcinoma of lung?

DR. BECKMAN'S DIAGNOSIS

Bronchial tuberculosis.

ANATOMICAL DIAGNOSES

Chronic pneumonitis.

Bronchiectasis, slight.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The lobectomy specimen showed a fibrous, rubbery lesion, measuring 10 by 5 by 5 cm., in the anterior portion of the lobe, with a number of dilated bronchi close by. There was no obstruction to the bronchus of this lobe. Microscopic examination of the scarred area showed chronic pneumonitis, with exactly the picture that Dr. Lord described and to which Dr. Means referred. It apparently was an organized pneumonia with a great deal of fibrosis in which there were tiny cavities filled with air, apparently distended respiratory ducts and atria, and a slight degree of secondary bronchiectasis. The whole process, I am certain, was due to the unresolved pneumonia. There was no evidence of tumor or tuberculosis.

DR. SWEET: I would like to emphasize the point which was touched upon before; namely, if one waits in every case for a positive bronchoscopic biopsy in cases of carcinoma of the lung, the opportunity for successful surgical removal is frequently lost. If we are to improve our results in this dread disease, it will be necessary to explore many cases such as this in order to catch a few early cases of carcinoma before it is too late.

This patient left the hospital feeling well; he was much happier than when he came.

CASE 30292

PRESENTATION OF CASE

A seventy-year-old Anglican priest entered the hospital because of severe substernal pain.

The patient had been in apparent good health until about two or four months before admission,

lung abscess, which do not seem probable, because he was in excellent health and had no evidence of constitutional disease — no fever and no loss of weight. If he had had a lung abscess and was not producing a large amount of sputum, one would expect fever and general constitutional symptoms. The other possibility along that line is that he developed pulmonary fibrosis, which seems to occur more frequently than we used to think, especially following a primary, atypical pneumonia. The other line of reasoning that one might pursue is that the patient had had some lesion in the lung prior to the illness and that the physical signs were present at that time and persisted through the acute illness without bearing a distinct relation to it. He might have had a benign bronchial adenoma that produced collapse of the lung and acute infection behind the obstruction or he might have had a malignant bronchial tumor. I do not believe that that is likely. There was a rather striking difference of opinion among the pathologists with respect to the biopsy. The clinical picture did not resemble that usually encountered in carcinoma of the lung. He had had no persistent cough and no hemoptysis. Also, if he had had cancer, I should not have expected his symptoms to regress in the way they did; it is more usual for a primary cancer of the lung to have a continuously downhill course. I shall agree with the pathologist who said that there was no malignant disease.

Perhaps Dr. Holmes can help us by interpreting the x-ray films.

DR. GEORGE W. HOLMES: The first film was taken in the usual manner, and the second with a grid to bring out the bronchi and the shadows that show in the lateral view as described in the text. This is typical of collapse of the lung. We have all the signs, namely, decrease in size, increased density in the involved area, displacement of the mediastinal contents toward the affected side, limitation of the respiratory movements of the diaphragm on the affected side and increased brilliancy in the portion of the lung below the affected area. Of course, these are statements made by the one who interpreted the film, and we have to take that into consideration in deciding.

We see here that there is obvious dullness at the right apex. It is not mottled, nor has it the character that one expects to see with old tuberculosis. Then we see along here a dense line that represents the border of the septum, and that is much too high. One can be quite certain that the picture represents a retracted lung; whether that was due to the shutting off of air by something in the bronchus or to a fibrotic process in the lung itself is not too clear. I should think that if it had been due to fibrosis in the lung itself there would be more of the signs of fibrosis in the lung. To me, this looks much more like a collapsed than a fibrotic lung.

Dr. Beckman mentioned the possibility of adenoma. In practically all our cases of benign adenoma the lesion has occurred in one of the large bronchi, not in a small one. This lesion, if it is an obstructing lesion, is not in one of the large bronchi; it would have to involve the small bronchi to produce the appearance. Furthermore, we can see the large bronchi fairly well, and they show no evidence of tumor.

DR. BECKMAN: What about the areas that were supposed to be filled with air?

DR. HOLMES: I should take that statement with a grain of salt. They may or may not represent something. They were possibly areas of lung that were not collapsed.

DR. BECKMAN: That is at least helpful to me, because I feel more secure in the fact that there was real atelectasis. Can you tell whether it was atelectasis or fibrosis? Perhaps that is not a fair question.

DR. HOLMES: My opinion is that it was atelectasis and not fibrosis, but it is not based on a great deal of evidence.

DR. BECKMAN: It is perfectly possible that he had pulmonary fibrosis following pneumonia, although I do not believe that it is likely. I am more in favor of a lesion that occluded some of the bronchi. There are several. I do not know which are the most frequent, but certainly there are various tumors that can do that, and then there is the case¹ that Dr. Helen Pittman discussed here some months ago — a bronchial tuberculosis with a lesion sufficiently large to occlude a bronchus and produce atelectasis. I should think that would have to be seriously considered here.

There is no information on the examination of the sputum.

DR. RICHARD H. SWEET: The sputum was examined a number of times, not here, but elsewhere, and nothing was found.

DR. BECKMAN: I am afraid that I am not sufficiently expert in lung diseases to do anything but guess concerning the nature of this lesion. I am helped a little bit by the fact that an operation was performed. I do not believe that anyone would operate on a patient with pulmonary fibrosis if they were able to make that diagnosis. If I had been handling this case, I should have wanted a bronchoscopy. Possibly that is the operation noted in the record. If anything was learned, it means that the lesion was something that could be seen through the bronchoscope and could be biopsied. As I said before, I have to guess, but shall say that the patient had bronchial tuberculosis, which had occluded one or several bronchi and had produced atelectasis.

DR. J. H. MEANS: Dr. Beckman showed me the abstract of the history this morning. I was interested and looked up in Dr. Lord's book² to see what he had to say about lung conditions that

monary infarction would cover all this. People with pulmonary infarction not uncommonly have jaundice, a palpable liver, an increased pulmonic second sound and substernal pain. They also have shortness of breath at rest. One thing to back this up is that there was evidence of varicose veins, which are liable to thrombosis.

I believe that the absent pulsations of the dorsalis pedis arteries were associated with a general arteriosclerotic process. Combined systemic disease, to account for the loss of reflexes, is hardly borne out by a red-cell count of 4,200,000 and an adequate hemoglobin. Some rare condition of the peripheral nerves, such as beriberi or avitaminosis, seems improbable because of the patient's general appearance. He was only mildly dehydrated. A dissecting aneurysm could account for the absence of the dorsalis pedis pulsations. I am quite certain, however, that if he had had enough of a dissecting aneurysm to occlude the aorta from without, he would have been in shock and unable to maintain a blood pressure of 186 systolic, 120 diastolic. The only characteristic feature of a dissecting aneurysm in this case is the sudden pain in the back. I doubt that that is a cause of lost circulation.

We then come to the x-ray examination, which shows evidence of the fluid of congestive failure, increased lung markings, an enlarged heart and a tortuous and sclerotic aorta. The slightly elevated blood nonprotein nitrogen (45 mg. per 100 cc.) probably goes with a general process of decompensation. The electrocardiogram is interesting if we are considering a diagnosis of angina pectoris, because there is no evidence of coronary occlusion. They speak of sagging in the ST segments in Leads 1 and 2, which is usually considered to be due to digitalis, and of course, this patient had been taking digitalis. The total inversion of Lead 3 was probably due to a high diaphragm, and there was inversion of the T waves in Lead 3, and slight elevation of the ST segments. In fact, this tracing shows very deep T waves in Lead 3. It is difficult to determine how much actual left-axis deviation there is, even in view of the large size of the heart. In view of the total inversion I am not quite ready to think that this single electrocardiogram represents unequivocal evidence of coronary thrombosis.

Apparently the congestive heart failure increased and the patient began to cough up blood. More rales were heard, and it was noticed that the substernal distress, pain as well as shortness of breath, I presume, was relieved by sitting up. I believe that the diagnosis of hypertensive heart disease is justifiable. He had generalized arteriosclerosis, and he had angina pectoris. In addition he had pulmonary infarcts, varicose veins with thrombosis, and chronic cholecystitis and cholelithiasis, which would account for the occasional pain of thirty years' duration.

DR. CONGER WILLIAMS: I saw this patient on just one occasion. At that time I wondered whether

at least some of his discomfort might have been due to orthopnea, because the statement was made that his pain was much worse on lying down and relieved by sitting up. Although it did not seem likely that all the discomfort was the result of orthopnea, it appeared reasonable that some was due to that as a result of congestive failure. Presumably he was in failure at that time.

DR. PAUL D. WHITE: I saw this man the day before he died. He had been in the hospital a week or so. I never saw a sicker man. He was breathing through an oxygen mask, complaining that he could not stand the discomfort of the substernal pain and of the dyspnea. There was an unusual combination of severe pain and severe dyspnea. He got some benefit from the oxygen, but not enough to give him real relief. There was obviously a good deal of pulmonary congestion, and the question arose, as discussed by Dr. McGinn, whether a pulmonary infarct superimposed on hypertensive and coronary heart disease was the better answer than a myocardial infarct. The electrocardiogram was taken on the second day, and several more days had elapsed before I saw him.

DR. BENJAMIN CASTLEMAN: He died on the ninth day.

DR. WHITE: Yes; I saw him on the eighth day, and as I have said, the only electrocardiographic record was taken on the second day. It was essentially negative except for sagging of the ST segments. That could be ascribed to digitalis, but the report is inadequate. This case is an illustration of the need of serial electrocardiograms and of more extensive precordial electrocardiograms in order to be more confident about the diagnosis. I asked for a second record when I saw him, but the patient died before it could be obtained. It would have been important to have had serial electrocardiograms or some precordial records, because one sometimes sees a normal Lead 4, perhaps taken a little inside the apex, and a very abnormal electrocardiogram in positions CF₄ and CF₆.

DR. CHESTER M. JONES: Was anything done about esophageal electrocardiograms? Is there any indication for them in patients not so sick as this man in whom there is doubt about coronary disease?

DR. WHITE: It is still largely a technic for experimentation, although certainly a posterior infarct may be demonstrated in that way. It would have been too difficult a procedure, and I expect not possible, in this patient. We still have an occasional chance to pick up posterior infarction by the precordial leads when recorded early or better still by serial limb leads.

CLINICAL DIAGNOSES

Myocardial infarction.
Pulmonary edema.

when he began to notice chest pain and shortness of breath on exertion, which were relieved by rest. The frequency of these attacks increased. About two weeks before entry, dyspnea and pain first appeared during rest, and in the few days before admission they became almost constant. The pain was substernal and radiated to the left shoulder and to the jaws and was accompanied by a cough.

One year before entry the patient had an unexplained fall, without loss of consciousness, fainting, weakness or visual disturbances preceding or following the fall. Since the age of thirty he had had occasional attacks of agonizing pain in the epigastrium during which he fell to the floor with paroxysms of pain. He could not tolerate fatty foods of any kind. He had not noted clay-colored stools, jaundice or changes in the urine.

Physical examination showed a dyspneic, somewhat icteric and mildly dehydrated man. The neck veins were prominent in a semireclining position. The lower thirds of both lung fields were slightly dull, and many rales were heard on auscultation. The left border of cardiac dullness was 12 cm. from the midline in the fifth space. The sounds were distant. There was reduplication of the second sound in both the aortic and mitral regions. The rate was regular, and there was no pulse deficit. The pulmonic second sound was greater than the aortic. A Grade II apical systolic murmur was heard. The liver edge was palpable one and a half fingerbreadths below the costal margin. Evidence of old varicose vein edema was seen in both lower legs. The dorsalis-pedis pulsations could not be felt. The knee and ankle jerks were absent. The tendon reflexes of the upper extremities were decreased.

The blood pressure was 186 systolic, 120 diastolic. The temperature was 100°F., the pulse 100, and the respirations 25 to 35.

Examination of the blood showed a red-cell count of 4,250,000, with 12.2 gm. of hemoglobin. The white-cell count was 16,600, with 82 per cent neutrophils. A blood Hinton test was negative. The urine was normal. The blood nonprotein nitrogen was 45.5 mg. per 100 cc.

An x-ray film of the chest showed enlargement of the heart in the region of the left ventricle. The transverse diameter of the heart was 16.7 cm., and the inner diameter of the chest 28.5 cm. A moderate amount of fluid was present in both pleural cavities. The hilar shadows were prominent, and the vascular markings were increased throughout both lungs. The aorta was tortuous but not dilated.

The patient was given 0.4 mg. of nitroglycerin, which relieved the pain. He was also given 100 mg. of Demerol intramuscularly and 6 cc. of Cedilanid subcutaneously, followed by 2 cc. in four hours, and he was placed on 0.1 gm. of digitalis daily. An electrocardiogram on the second hospital day showed normal rhythm, with a rate of 110. There was total inversion in Lead 3. The ST segments in Leads 1

and 2 were sagging. The T waves in Lead 3 showed late inversion; Lead 4 looked good.

The patient was unable to sleep or rest because of shortness of breath and substernal discomfort. The anginal pains were fairly well controlled by Demerol. He continued to cough and to raise a small amount of blood. The pulse remained rapid. On the fifth hospital day the lungs showed an increase in the moisture in the bases, and there was some pitting edema of the ankles. He was given 2 cc. of Mercupurin intravenously for two days. The substernal distress seemed to be relieved by sitting up, but his condition continued to fail, and he died on the ninth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. SYLVESTER MCGINN: No single diagnosis that I can think of seems adequate to cover everything in this case, and a number of the symptoms have to be analyzed separately.

First, I should like to speak of the dyspnea, the shortness of breath and pain in the chest coming on with exertion and, a short period of time after that, the shortness of breath at rest. There is no note whether this dyspnea at rest came on suddenly, or whether it occurred in paroxysms, such as cardiac asthma. Later on it is apparent that there was left ventricular weakness, and one might anticipate that there had been cardiac asthma. Then we come to the substernal pain on exertion, relieved by rest and nitroglycerin. Later the pain was constant and came when at rest. Immediately the anginal syndrome is suggested. This man was having midepigastric pain of some severity over a thirty-year period, which occasionally forced him to bend over and fall to the floor. When people assume the knee-chest position and have deep midepigastric pain one thinks of pancreatitis. Since the attacks were repeated, it is quite possible in this case that the patient had chronic cholecystitis with the passage of small calculi, giving biliary colic. We do not know how often these pains occurred, but that is the diagnosis that most adequately covers these attacks.

In the physical examination several features stand out. One thing is definite — the blood pressure of 186 systolic, 120 diastolic. Again, there is evidence that, by percussion, the heart was enlarged in the region of the left ventricle. Other evidence of right-heart strain is shown by increased fullness of the left cervical veins and the fact that the pulmonic second sound was greater than the aortic early, even though the patient had hypertension. We also find that the liver was palpable one and a half fingerbreadths below the costal margin and that there was a moderate grade of jaundice. There are several conditions that could cause acute or even chronic right-heart strain. I am assuming that something happened two weeks prior to entry that was a little different from the previous illness. Pul-

monary infarction would cover all this. People with pulmonary infarction not uncommonly have jaundice, a palpable liver, an increased pulmonic second sound and substernal pain. They also have shortness of breath at rest. One thing to back this up is that there was evidence of varicose veins, which were liable to thrombosis.

I believe that the absent pulsations of the dorsalis pedis arteries were associated with a general arteriosclerotic process. Combined systemic disease, to account for the loss of reflexes, is hardly borne out by a red-cell count of 4,200,000 and an adequate hemoglobin. Some rare condition of the peripheral nerves, such as beriberi or avitaminosis, seems improbable because of the patient's general appearance. He was only mildly dehydrated. A dissecting aneurysm could account for the absence of the dorsalis pedis pulsations. I am quite certain, however, that if he had had enough of a dissecting aneurysm to occlude the aorta from without, he would have been in shock and unable to maintain a blood pressure of 86 systolic, 120 diastolic. The only characteristic feature of a dissecting aneurysm in this case is the sudden pain in the back. I doubt that that is a cause of lost circulation.

We then come to the x-ray examination, which shows evidence of the fluid of congestive failure, increased lung markings, an enlarged heart and a tortuous and sclerotic aorta. The slightly elevated blood nonprotein nitrogen (45 mg. per 100 cc.) probably goes with a general process of decompensation. The electrocardiogram is interesting if we are considering a diagnosis of angina pectoris, because there is no evidence of coronary occlusion. They speak of sagging in the ST segments in Leads 1 and 2, which is usually considered to be due to digitalis, and of course, this patient had been taking digitalis. The total inversion of Lead 3 was probably due to a high diaphragm, and there was inversion of the T waves in Lead 3, and slight elevation of the ST segments. In fact, this tracing shows very deep T waves in Lead 3. It is difficult to determine how much actual left-axis deviation there is, even in view of the large size of the heart. In view of the total inversion I am not quite ready to think that this single electrocardiogram represents unequivocal evidence of coronary thrombosis.

Apparently the congestive heart failure increased and the patient began to cough up blood. More rales were heard, and it was noticed that the substernal distress, pain as well as shortness of breath, I presume, was relieved by sitting up. I believe that the diagnosis of hypertensive heart disease is justifiable. He had generalized arteriosclerosis, and he had angina pectoris. In addition he had pulmonary infarcts, varicose veins with thrombosis, and chronic cholecystitis and cholelithiasis, which would account for the occasional pain of thirty years' duration.

DR. CONGER WILLIAMS: I saw this patient on just one occasion. At that time I wondered whether

at least some of his discomfort might have been due to orthopnea, because the statement was made that his pain was much worse on lying down and relieved by sitting up. Although it did not seem likely that all the discomfort was the result of orthopnea, it appeared reasonable that some was due to that as a result of congestive failure. Presumably he was in failure at that time.

DR. PAUL D. WHITE: I saw this man the day before he died. He had been in the hospital a week or so. I never saw a sicker man. He was breathing through an oxygen mask, complaining that he could not stand the discomfort of the substernal pain and of the dyspnea. There was an unusual combination of severe pain and severe dyspnea. He got some benefit from the oxygen, but not enough to give him real relief. There was obviously a good deal of pulmonary congestion, and the question arose, as discussed by Dr. McGinn, whether a pulmonary infarct superimposed on hypertensive and coronary heart disease was the better answer than a myocardial infarct. The electrocardiogram was taken on the second day, and several more days had elapsed before I saw him.

DR. BENJAMIN CASTLEMAN: He died on the ninth day.

DR. WHITE: Yes; I saw him on the eighth day, and as I have said, the only electrocardiographic record was taken on the second day. It was essentially negative except for sagging of the ST segments. That could be ascribed to digitalis, but the report is inadequate. This case is an illustration of the need of serial electrocardiograms and of more extensive precordial electrocardiograms in order to be more confident about the diagnosis. I asked for a second record when I saw him, but the patient died before it could be obtained. It would have been important to have had serial electrocardiograms or some precordial records, because one sometimes sees a normal Lead 4, perhaps taken a little inside the apex, and a very abnormal electrocardiogram in positions CF₄ and CF₆.

DR. CHESTER M. JONES: Was anything done about esophageal electrocardiograms? Is there any indication for them in patients not so sick as this man in whom there is doubt about coronary disease?

DR. WHITE: It is still largely a technic for experimentation, although certainly a posterior infarct may be demonstrated in that way. It would have been too difficult a procedure, and I expect not possible, in this patient. We still have an occasional chance to pick up posterior infarction by the precordial leads when recorded early or better still by serial limb leads.

CLINICAL DIAGNOSES

Myocardial infarction.
Pulmonary edema.

DR. MCGINN'S DIAGNOSES

Hypertensive heart disease.
 Arteriosclerosis, generalized.
 Angina pectoris.
 Pulmonary infarcts.
 Thrombosis: leg veins.
 Chronic cholecystitis and cholelithiasis.

ANATOMICAL DIAGNOSES

Coronary thrombosis, recent, right.
 Myocardial infarction, recent: left ventricle.
 Pericarditis, acute, fibrinous.
 Cardiac hypertrophy, hypertensive type.
 Pulmonary edema and congestion.
 Hydrothorax, bilateral.
 Peripheral edema, slight.
 Arteriosclerosis, generalized.
 Cor pulmonale?
 Pulmonary atelectasis, bilateral.
 Esophageal varices.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed a heart weighing over 600 gm., with an enlarged left ventricle and a thick right ventricle, measuring 6 mm.

DR. WHITE: That would help to balance the electrical axis. In other words, it is possible that he had enough left ventricular failure to give him some right ventricular hypertrophy, or there may have been some other cause in the lungs.

DR. CASTLEMAN: The medium-sized arteries in the lungs were definitely hypertrophied, but there was no cause that we could find for that.

In the heart there was an extremely large posterior infarct involving the apex; this must have been quite recent because of a large number of polymorphonuclears within it, but organization was progressing.

DR. WHITE: How old was it? A few days, or older?

DR. CASTLEMAN: About two weeks.

DR. WHITE: It was probably present when he entered the hospital?

DR. CASTLEMAN: Yes. The cause of the infarction was a large thrombus of the right coronary artery, beginning about 5 cm. from the origin of the artery and measuring 6 cm. in length. It was one of the longest coronary thrombi that I have seen.

DR. WHITE: I suppose that with the progression of this infarct, one might have expected an inversion of T₂.

DR. CASTLEMAN: The gall bladder was normal. The lungs showed atelectasis in addition to moderate medial hypertrophy of the small arteries. I do not suppose that the process was extensive enough to call Ayerza's disease, but it probably accounted somewhat for the right ventricular hypertrophy.

DR. JONES: Was there any other evidence of previous thrombosis?

DR. CASTLEMAN: The coronary arteries showed extreme sclerosis, such as one sees in patients with angina.

DR. WHITE: Was there any explanation of the pain in the epigastrium?

DR. CASTLEMAN: No. We found nothing in the gastrointestinal tract except four or five varices in the lower end of the esophagus, with no cirrhosis, the cause of the varices was undetermined.

DR. JONES: That is impressive because it is rare to find so-called "congenital varices," or I suppose a better term is "varices, cause unknown." I do not believe that they would give symptoms. There was no difficulty in swallowing. That is an interesting anatomical finding without explanation. He did not have a hernia?

DR. CASTLEMAN: None that was apparent. Unless definitely looked for, however, a hiatus hernia can be easily overlooked.

He had acute pericarditis secondary to the infarction. Do you think that might affect the electrocardiogram, Dr. White?

DR. WHITE: There was not enough wrong in his one record to suspect it.

DR. McGinn brought up the matter of hypertension and that is one point to which attention should be called. The blood pressure often comes down during pain from acute myocardial infarction, but not infrequently the reverse is true, and occasionally we have seen a higher pressure than that at any other time, either before or after.

DR. JONES: How long does it persist after thrombosis has taken place—twenty-four to thirty-six hours?

DR. WHITE: It subsides in a few hours or in a day or two; but it is a point that may lead one astray if one always expects a drop in blood pressure in coronary thrombosis.

ANNUAL MEETING OF THE AMERICAN MEDICAL ASSOCIATION

AFTER an interval of two years the American Medical Association again held its annual meeting, this time in Chicago on June 12, 13, 14, 15 and 16. In spite of the difficulties of travel and anxieties at home the registration was about normal. The section meetings were, for the most part, crowded. The programs were varied and interesting. Although the scientific exhibit was perhaps not quite so large as usual, it maintained its usual standard.

The House of Delegates convened on Monday, with an attendance of 170 out of a possible 175. The secretary of the Association again reported an in-

crease in membership. There are now 124,452 members, against 122,741 in 1942. Deaths of members have increased, however, there having been 2019 during the year. About half these deaths were due to some form of cardiac disease and about half the cardiac deaths were caused by disease of the coronary arteries. This perhaps is an indication of the tempo at which civilian physicians are now working.

The House listened to reports of its officers, the Board of Trustees and the various councils and committees. The address of the president, James E. Paullin, should be read with care. It gives an idea of the vast amount of work being done by various unpaid committee members during these trying times, in spite of all they have to do in their own practices. His closing remarks were a plea for unity within the organization:

It is only by the development of complete unity and support that the views of the medical profession, which have been developed for the best interests of the public and for the advancement of science, can be made to prevail. If the purposes and ideals and desires for which we as a medical profession stand are worth while, then there should be the loyal support of every member of all organizations to see that they prevail.

Dr. Herman L. Kretschmer, president-elect, stressed the need of further education of the public regarding medical economics, particularly by general practitioners in their local communities.

Probably the most important action taken by the House of Delegates was the dispatch of a telegram to various authorities in Washington protesting the curtailment of the Specialized Army Training program as it pertains to premedical and medical students. This was considered to be the most serious situation confronting the medical profession today, since it is not possible to fill the enrollment of medical schools with women and physically disqualified men. If enough doctors to offset an approximate annual deficit of 2000 are to be obtained, some way to defer premedical students from the draft must be found.

Much was said about postwar planning. It was recommended that a central bureau be established in Chicago to provide information to physicians returning from service concerning internships, residencies, fellowships, postgraduate courses and so forth. It was stated that the experience gained

in the wartime graduate meetings that have been held so successfully in numerous military hospitals might provide a pattern for future postgraduate teaching.

The House was honored by the presence of Surgeon General Kirk of the Army Medical Corps, and of Surgeon General McIntire of the Navy Medical Corps, both of whom addressed the meeting and were enthusiastically received.

The climax for the Massachusetts delegation came, however, in the privilege of presenting Dr. Roger I. Lee's name for the office of president-elect. The enthusiasm with which the nomination was received and the prompt and unanimous election attest the high regard in which Dr. Lee is held by the House of Delegates. With ten years of service as a trustee, few men have come so well equipped for this exacting and important position. Again, Massachusetts has cause to rejoice.

THE OUTLOOK FOR MENINGOCOCCAL MENINGITIS

EPIDEMICS of meningococcal meningitis are known to occur irregularly in cycles, which usually last from two to five years. There are, in addition, secondary rises and falls in incidence, with peaks occurring during the fall and winter of each year within a large epidemic cycle. During the course of an epidemic a comparison of the incidence of the disease at any time of the year with its occurrence during the corresponding period of the preceding year may therefore give some clue whether the epidemic is waxing or waning, and in this way one may predict whether more or fewer cases are to be expected during the following year and even during the succeeding weeks and months.

A recent summary of the incidence of meningitis, which is included among the morbidity reports of notifiable diseases,¹ indicates that there were more cases during the year 1943 than in 1942. A total of 612,068 cases were reported during the former, and 546,023 cases during the latter. The provisional mortality figures for the first nine months of 1943 show more strikingly the increase in the disease that occurred during that period over the corresponding months of the two previous years.² The mortality in thirty-

eight states during 1943 was 2.0 per 100,000 population, as compared with 0.6 during 1942 and 0.5 during 1941. There were deviations from these figures in certain parts of the country, but the great majority of states had rates that were quite similar both qualitatively and quantitatively. Notable exceptions are Pennsylvania and Montana: in the former the mortalities were respectively two and a half and three and a half times as great in 1942 and 1943, and in the latter the 1943 figure was 8.0 deaths per 100,000 population, compared with 0.4 for each of the two previous years.

More recent figures, however, offer encouraging evidence that the epidemic is subsiding or at least is beginning to decline. In the morbidity report for the week ending March 11, 1944,³ the weekly incidence of meningococcal meningitis was lower than that for the corresponding week last year, this being the first time that a decline had been noted. Subsequent reports⁴ showed that the downward trend continued during four successive weeks, but during the week ending April 22, the incidence was slightly higher than in the previous year. Such slight irregularities are to be expected, owing to variations in the occurrence of the disease in different parts of the country, and do not necessarily interfere with the general trend of the epidemic incidence; in fact, the very next report⁵ indicated that the downward swing was continuing.

Although the epidemic appears to be subsiding, there will undoubtedly be appreciable numbers of cases of meningococcal meningitis during the coming fall and winter, with a peak that will be appreciably lower than that of the past year. Physicians must still be on the lookout for cases and must treat them early and adequately with sulfonamide drugs to keep the mortality at a minimum. One should also be on the lookout for cases of meningococcemia without meningitis, since such patients respond promptly to sulfonamide therapy and since early treatment usually forestalls meningitis and other focal complications, such as arthritis and endocarditis.

MASSACHUSETTS MEDICAL SOCIETY

THE BLUE SHIELD

While countless and voluminous opinions were expressed concerning legislative proposals for legalized medicine, the sponsors of the Blue Shield sought out the causes for such bills and attempted to neutralize them by more answerable methods.

The Blue Shield in Massachusetts now numbers nearly 35,000 members. Employee groups have been formed in 432 industrial and business organizations. Although more than 3300 Massachusetts doctors have become participating physicians, there are still many members of the profession who have not yet agreed to take an active part in the plan.

Some doctors object to having Blue Shield put a price on their services to the patient. These men should realize, however, that only the low-income subscriber is affected by the set fees, and as time goes on, 100 per cent collections obtainable through Blue Shield will create a better situation than higher fees and 50 to 80 per cent collections. Blue Shield subscribers in the upper-income brackets may be charged by the doctor with the difference between the amount specified in the fee schedule and his regular fee.

A few busy physicians fear that under Blue Shield they would have to serve many more patients than they have time for at present. Such fears are unfounded because Blue Shield guarantees the free choice of patients and in no manner does it insist on doctors taking Blue Shield subscribers as patients whom they would not ordinarily treat.

Several doctors state that they do not agree with the principles of a prepayment plan. This viewpoint is held by an extremely small minority, and is gradually changing to that of the leading physicians in the country, who realize that prepayment is the only answer to a better distribution of medical care. Such doctors may also remember that if the solution to the problem becomes impossible on a voluntary basis, the people themselves, who have already gone on record as desiring an easier method of paying their doctors' bills, will make decisions arbitrarily through legislation.

The Blue Shield is still in its infancy. Its growth has been satisfactory, but if the public demand is to be satisfied, the Blue Shield must receive the same whole-hearted support from physicians that the Blue Cross has obtained from its member hospitals. The latter is now adding members at the rate of a thousand a day.

If you are not yet a Blue Shield participating physician, you are urged to write to the Blue Shield office at 230 Congress Street, Boston 6, for further information.

DEATH

MOODY — Flora F. Moody, M.D., of Springfield, died June 26. She was in her seventy-fourth year.

Dr. Moody received her degree from Tufts College Medical School in 1898. She was a member of the American Medical Association and the Springfield Woman's Medical Club.

Her husband, a son, three sisters and a brother survive.

WAR ACTIVITIES

POSTWAR PLANNING

BUREAU OF MEDICAL EDUCATION CREATED BY NEW YORK ACADEMY OF MEDICINE

Anticipating an unprecedented demand for postgraduate medical education on the termination of war, particularly from physicians returning to civil life from service in the armed forces, and from civilian physicians from Central and South America, as well as from European countries released from Nazi control, the New York Academy of Medicine has created the Bureau of Medical Education.

The function of this bureau will be to serve all physicians interested in furthering their medical knowledge, but particularly physicians returning from the war, and the increasing numbers of foreign physicians who come to New York for postgraduate instruction and training. It will be organized by and operated under the supervision of the Committee on Medical Education of the New York Academy of Medicine and will render its services without charge. One of its chief functions will be to publish announcements of postgraduate medical courses conducted by the universities and the hospitals of New York City. Thirty-three of the leading hospitals have been invited to collaborate in this undertaking, and advisers representing the special fields of medical practice have been appointed to supervise the work of the bureau.

MISCELLANY

DEPARTMENT OF MEDICAL SCIENCES ESTABLISHED AT BROWN UNIVERSITY

The establishment of the Department of Medical Sciences at Brown University was recently announced by President Henry M. Wriston. This department will perform a number of important functions within the University and in the relations of the University to the medical profession and hospitals of the community. Charles A. McDonald, M.D., and Alex M. Burgess, M.D., physicians connected with the Division of University Health for some time, have been appointed professors of health and hygiene in this new department.

Dr. Wriston pointed out that through this department the University will assume a larger responsibility for the general education of its students in matters of health as a requisite of effective accomplishment in college and after-college years. He went on to say that special attention will be given to the orientation of students who are planning to enter the medical profession and that the department will offer facilities for advanced study and research, being designed in part to meet the needs and desires of recent graduates of medical schools whose postgraduate studies in certain specialized fields of medical science have been interrupted by war service. Dr. Wriston stated that opportunities for specialized study will also be available to other interested members of the medical profession, emphasizing that the University will be prepared to co-operate in the development of programs of postgraduate study and research for members of the resident staffs of the hospitals of the community.

CORRESPONDENCE

NEW POLICIES OF BOARD OF REGISTRATION IN MEDICINE

To the Editor: On May 17, 1944, the Board of Registration in Medicine voted unanimously that it shall be the policy of the Board, following a hearing, to revoke or suspend, as

in the wartime graduate meetings that have been held so successfully in numerous military hospitals might provide a pattern for future postgraduate teaching.

The House was honored by the presence of Surgeon General Kirk of the Army Medical Corps, and of Surgeon General McIntire of the Navy Medical Corps, both of whom addressed the meeting and were enthusiastically received.

The climax for the Massachusetts delegation came, however, in the privilege of presenting Dr. Roger I. Lee's name for the office of president-elect. The enthusiasm with which the nomination was received and the prompt and unanimous election attest the high regard in which Dr. Lee is held by the House of Delegates. With ten years of service as a trustee, few men have come so well equipped for this exacting and important position. Again, Massachusetts has cause to rejoice.

THE OUTLOOK FOR MENINGOCOCCAL MENINGITIS

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

A National Health Service. By Alice Bush, M.D.; J. McMur-ray Cole, M.D.; E. F. Fowler, M.D.; Elizabeth Hughes, M.D.; Howard Gaudin, M.D.; Selwyn Morris, M.D.; Bruce Mackenzie, M.D.; and Douglas Robb, M.D. 12°, paper, 108 pp. Wellington, New Zealand: Progressive Publishing Society, 1943. 2/6.

In this small pamphlet will be found a description of a plan for the National Health Service in New Zealand. Its practical application is worked out for Auckland City and its suburbs, detail being given in four appendices.

The Nature and Treatment of Mental Disorders. By Dom Thomas V. Moore, O.S.B., Ph.D., professor of psychology and psychiatry, Catholic University of America. With a foreword by Edward A. Strecker, M.D., professor of psychiatry, Graduate and Undergraduate Schools of Medicine, University of Pennsylvania, and consultant and chief of service, Institute of the Pennsylvania Hospital, Pennsylvania. 8°, cloth, 312 pp. New York: Grune and Stratton, 1943. \$4.00.

This is a new manual on clinical psychiatry in which emphasis is placed on treatment. The author has appended a classification and definition of clinical entities of psychiatry.

Manual of Fractures: Treatment by external skeletal fixation. By C. M. Shaar, M.D., captain, Medical Corps, United States Navy; and Frank P. Kreuz, Jr., M.D., lieutenant commander, Medical Corps, United States Navy. 8°, cloth, 300 pp., with 148 illustrations. Philadelphia: W. B. Saunders Company, 1943. \$3.00.

This manual describes fully the new treatment of external fixation of fractures, which is ideal for use at sea and in mobile hospitals where transportation of patients becomes necessary.

Elements of Medical Mycology. By Jacob H. Swartz, M.D., assistant professor of dermatology, Harvard Medical School and Postgraduate School, and dermatologist, Massachusetts General Hospital. With an introduction by Fred D. Weidman, M.D., professor of dermatological research, University of Pennsylvania. 8°, cloth, 179 pp., with 78 illustrations. New York: Grune and Stratton, 1943. \$4.50.

This small manual is designed to serve as a guide to the study of fungus diseases.

The Dysenteric Disorders: The diagnosis and treatment of dysentery, sprue, colitis and other diarrhoeas in general practice. By Sir Philip Manson-Bahr, C.M.G., D.S.O., M.D., F.R.C.P., senior physician to the Hospital for Tropical Diseases and the Royal Albert Dock and Tilbury hospitals, consulting physician in tropical diseases to the Dreadnought Seamen's Hospital, London, director, Division of Clinical Tropical Medicine, London School of Hygiene and Tropical Medicine, consulting physician to the Colonial Office and Crown Agents to the Colonies, consultant in tropical medicine to the Admiralty and to the Royal Air Force, and Lumleian Lecturer, Royal College of Physicians, 1941. With an appendix by W. John Muggleton, M.S.M., F.I.M.L.T., technical assistant. Second edition. 8°, cloth, 629 pp.,

with 23 plates and 108 illustrations. Baltimore: The W and Wilkins Company, 1943. \$10.00.

The first edition of this book was printed in 1939, and the second edition has been called for by the necessity of including many advances in etiology, diagnosis and treatment that have become available since its first publication. No drastic alterations have been made in the arrangement of the book, but much new knowledge has been incorporated in its proper place throughout the various chapters. A new chapter on pellagra has been inserted, and the etiology of the sprue syndrome and its relation to steatorrhea. Discussion of the treatment of bacillary dysentery with sulfaguanidine has been included.

NOTICES

MEDICOLEGAL CONFERENCE AND SEMINAR

The Massachusetts Medico-Legal Society in conjunction with the medicolegal departments of Harvard, Boston University and Tufts medical schools has arranged for an annual day conference to be held at the Mallory Institute of Pathology, Boston City Hospital, on Wednesday, October 19, 1944. It will include lectures, demonstrations, and informal discussions concerning many subjects in legal medicine, particularly stressing some of the more recent procedures. The meeting will be open to any registered physician, law police official, senior medical student or other medical investigator who may be interested and care to register. A limit in number has been made. There will be no fee for registration. Although advance application is not essential it would be helpful to those arranging the conference. Notice of intention to attend be sent prior to October 1 to Dr. W. H. Watters, Department of Legal Medicine, Harvard Medical School, Boston 15.

The Harvard Medical School, Courses for Graduates, with the co-operation of the medical schools of Boston University and Tufts College, offers a seminar in legal medicine to occur the entire week of October 2 to 7, inclusive. It is planned particularly for medical examiners and coroners' physicians but will be open to any other suitable graduate of an approved medical school. The course will be practical rather than theoretical and will consist of autopsy demonstration technique and interpretation of laboratory tests, study of 1 day-by-day cases of a medical examiner, round-table conferences, and the many subjects now included in the wide field of legal medicine. In order that each participant may receive the maximum benefit, the enrollment has been limited to fifteen. For the seminar the fee is \$25. Application should be made on or before October 1 to Harvard Medical School, Courses for Graduates, 25 Shattuck Street, Boston 15.

NEW YORK INSTITUTE OF CLINICAL ORAL PATHOLOGY

The New York Institute of Clinical Oral Pathology announces its first open meeting, to be held at the New York Academy of Medicine on Monday evening, October 30, Hosack Hall. Outstanding investigators will participate in a symposium "Fluorine and Dental Caries."

Members of the medical, dental, public-health and other professional groups are cordially invited. For further information all communications should be addressed to Roistacher, Executive Secretary, 101 East 79th Street, New York 21, New York.

INFECTIOUS MONONUCLEOSIS SIMULATING BRUCELLOSIS*

A. DANIEL RUBENSTEIN, M.D., M.P.H.,† AND CAROLYN I. SHAW, Sc.B.‡

BOSTON

ALTHOUGH clinical and laboratory methods for the recognition of both infectious mononucleosis and brucellosis are reasonably adequate, differential diagnosis of these infections at times is subject to considerable confusion. Brucellosis, a bacterial disease, and mononucleosis, probably caused by a virus,¹ nevertheless present such similarities in their manifestations that one may readily be mistaken for the other.

In both diseases, fever of undetermined origin is usually the keynote of the clinical course. The presence of sore throat, lymphadenopathy and splenic enlargement suggests a diagnosis of infectious mononucleosis, which may be confirmed by blood studies and the heterophile antibody reaction. Except perhaps for varying degrees of leukopenia, most cases of undulant fever present no significant physical findings. The blood agglutination test is the one most frequently employed to corroborate the clinical impression. Unfortunately, isolation of the etiologic agent from the blood stream, the most reliable diagnostic aid, is not always successful. This is particularly true of infections caused by *Brucella abortus*.

Investigation of cases of undulant fever reported to the Massachusetts Department of Public Health has demonstrated at times a readiness to accept the agglutination reaction as the ultimate criterion in the diagnosis of this disease. It must, however, be borne in mind that a positive test may be indicative either of present infection or of previous exposure to the causative agent. Menefee and Johnston² have shown that a high titer of agglutinins may be demonstrated in the serums of patients with febrile diseases other than brucellosis.

In our experience, careful study of cases with positive agglutination reactions for undulant fever has occasionally revealed some other disease as the cause of an obscure hyperpyrexia. Recently a diagnosis of infectious mononucleosis was established in several such cases. With awareness of the similarity between these infections, it became

apparent that a certain percentage of cases suspected of being undulant fever might easily turn out to be infectious mononucleosis. Accordingly, it was decided to perform the heterophile antibody reaction routinely on a series of 1000 consecutive blood serums submitted by physicians to the State Bacteriological Laboratory for undulant-fever agglutination tests.

In each case in which a positive sheep-cell agglutination was elicited, the physician was interviewed to obtain additional laboratory and clinical data. If white-cell counts and blood smears were not already available, it was suggested that these examinations be made. In the cases in which the titer was less than 1:128, a second specimen was requested to ascertain the titer later in the course of the illness.

LABORATORY OBSERVATIONS

The number of specimens tested each month from May through October, 1943, and the number of positive sheep-cell and *Br. abortus* agglutinations are shown in Table 1. Each positive test represents

TABLE 1. Heterophile Antibody Reaction in Blood Serums Submitted for Undulant-Fever Agglutination Tests.

MONTH	NO. OF SERUMS TESTED	NO. OF POSITIVE HETEROPHILE ANTIBODY REACTIONS (1:128 or higher)	NO. OF POSITIVE UNDULANT-FEVER AGGLUTINATION TESTS (1:405 or higher)

September	144	0	5
October	158	4	5
Totals	1000	13	36

a final diagnosis of either undulant fever or infectious mononucleosis. All tests on questionable cases have been omitted. In the 1000 specimens, infectious mononucleosis was revealed in 13. In only 2 of these cases had this diagnosis been suspected by the physician who submitted the specimen; in other words, in 11 cases, this diagnosis might not otherwise have been revealed. It must be pointed out that a large proportion of the original

specimens were from patients with symptoms of long duration, the physician evidently having considered a diagnosis of chronic brucellosis. Since infectious mononucleosis is usually an acute, comparatively brief febrile illness, it was scarcely expected to find positive heterophile reactions among this group of cases. If these chronic infections had been excluded, the percentage of cases of infectious mononucleosis would have been appreciably greater.

This test series revealed only 36 cases of brucellosis. Since these specimens had been submitted specifically for undulant fever, the discovery of 13 cases of infectious mononucleosis represents by comparison a fairly high yield.

The cases of infectious mononucleosis are summarized in Table 2. In 2 cases (Cases 1 and 3), an

For this reason the total number of lymphocytes and monocytes was expressed as a percentage the mononuclear cells (Table 2), which varied from 50 to 90 per cent (considering only the highest percentage in each case). The known duration of fever varied from ten to twenty-three days. Cervical adenopathy was encountered in 7 cases, cervical lymphadenopathy in 10, and enlargement of the spleen in

EPIDEMIOLOGIC OBSERVATIONS

Brucellosis

The diagnosis of infectious mononucleosis rests on criteria that are fairly clearly defined. This is true of brucellosis unless the blood culture is positive. In contrast to the ambiguity associated with

TABLE 2. Summary of Laboratory and Physical Findings in 13 Cases of Infectious Mononucleosis

PATIENT	AGE	SEX	TITER OF SERUM	WHITE-CELL COUNT	PERCENTAGE OF MONONUCLEARS	SORE THROAT	ADENOPATHY	SPLenic ENLARGEMENT	DURATION OF FEVER
				$\times 10^3$					days
I M	21	I	1:64 1:1024	4.7 (Aug 17) 16.5 (Aug 21)	55 77	—	Cervical	+	15

D B	25	M	1:128	6.5 (Sept 17) 18.0 (Sept 27) 8.6 (Oct 18)	42 80 52		Posterior cervical	+	12
M B	20	I	1:1024	21.5	54		Posterior cervical	—	
L C	12	F	1:256	20.0 (Sept 9) 23.0 (Sept 17)	68	+	Cervical	—	10
L B	—	F	1:32,768	9.0	76	+	Cervical	—	9
N B	18	F	1:256	14.0	54		Posterior cervical	—	21
L L	34	M	1:512	16.3 (Oct 7) 22.9 (Oct 14) 22.1 (Oct 21)	74 77 78		Posterior cervical	—	14

initial test positive in a dilution of 1:64 rose to a higher titer in a subsequent specimen — 1:1024 in one case and 1:256 in the other. The highest titer obtained was 1:32,768, and 2 cases demonstrated positive reactions in a serum dilution of 1:2048. It is apparent that a titer of 1:64 is fair evidence of infectious mononucleosis. One case positive in this dilution (not included in Table 2), however, did not prove to be infectious mononucleosis.

White-cell counts were made in 12 cases and blood smears were examined in 13. The former ranged from 7200 to 23,000 (considering only the highest count in each case). Since the blood smears were performed in many laboratories, no conclusion could be drawn concerning specific blood cells.

its clinical manifestations, the epidemiology of undulant fever has been fairly definitely established.

Brucellosis is acquired by ingestion of infected dairy products or by contact with infected animals. In rare cases water has been incriminated as source.³ It has been observed that when a report of undulant fever cannot be traced either to raw milk or to potentially infected animals, review of the clinical findings may result in a change of diagnosis. In this manner epidemiologic investigations may become helpful in the diagnosis of undulant fever.

In Table 3 are summarized the sources of infection in 32 cases of undulant fever occurring in an urban state health district (North Metropolitan

strict). Of 18 cases traced to raw milk, 16 were traced by persons traveling outside this district. As a matter of fact, the amount of unpasteurized milk sold in this area is exceedingly small. Only 2 patients became infected from raw milk acquired within it.

On the other hand, out of 14 cases contracted within the area, 12 were traced to contact with humans or animal products, the infection having been acquired as a result of occupational exposure.

TABLE 3. *Sources of Infection in Cases of Undulant Fever Occurring in an Urban District (1930-1943).*

SOURCE	No. OF CASES
From milk	16
Outside district	2
Within district	7
Direct contact with animals	5
Indirect contact with animals or animal products	2
Unknown	2
Total	32

Direct contact with animals or animal carcasses by farmers, veterinarians or packing-house employees counted for 7 of these cases. Three patients were machinists in rendering plants and 2 were metal workers in packing houses. In each of these 5 cases the worker had handled machinery or other materials used in the processing of meat products, but no story of direct contact with animals or animal products could be elicited. All 5 cases occurred in plants where the attack rates for undulant fever among employees constantly handling carcasses or meat products were exceedingly low. Purriel et al.⁴ have found positive skin reactions for brucellosis among a large proportion of employees handling animal carcasses. It may be postulated that many of these workers develop immunity through long-continued exposure to the infectious agent. On the other hand, employees such as machinists, rarely in contact with the causative organisms, are more susceptible to a single chance exposure.

Infectious Mononucleosis

Since the etiology of infectious mononucleosis is not yet known, information concerning its epidemiology has been slowly accumulated. Since 1926, there has been a great deal of speculation concerning the possible etiologic relation of organisms of the genus *Listerella* to infectious mononucleosis in human beings.⁵ Janeway and Dammin⁶ investigated this question in 1941 by studying in patients with infectious mononucleosis the development of agglutinins against either of the two known groups of *Listerella*. Their observations suggested no relation between infectious mononucleosis and *Listerella* organisms.

Recently, Nettleship¹ recovered a virus from the blood and nasal washings of patients with infectious mononucleosis by inoculating sterile Berkefeld filtrates into the chorioallantoic membrane of the

chick embryo. Van den Berghe and Liessens^{7, 8} also considered the causative agent to be a virus, which they obtained in tissue culture. They reproduced the disease in monkeys, which later showed the typical blood picture and heterophile reaction.

Bernstein⁹ in an excellent review of the literature on infectious mononucleosis states that cases have been reported from all parts of the world. The disease occurs both sporadically and in epidemics. Outbreaks have taken place in schools^{10, 11} and in the general community.¹² The disease is well known to college physicians everywhere. With the exception of outbreaks in the Army,¹³ epidemics have not been found in any group above college age. During an outbreak, the resistance to the disease of persons in the older age groups may be quite striking.¹¹ It is well known that infectious mononucleosis is largely a disease of children and young adults. With the exception of a patient forty years old, all our patients were between the ages of twelve and thirty-four. Davis¹⁴ described an epidemic in an infants' ward.

Sporadic cases have been encountered during every month of the year. In a reported series⁹ the greatest incidence occurred in October. In some epidemics the attack rates are apparently quite high, but sporadic cases rarely give rise to secondary infections. Most hospitals admit cases of infectious mononucleosis to the open ward.

Of the 6 cases reported below, Cases 1 and 3 demonstrate the marked similarity between infectious mononucleosis and undulant fever. In each of the others an unusual feature of one or the other of these infections is described.

CASE REPORTS

CASE 1. D. B., a 25-year-old medical student, consulted his physician because of severe headache, prostration and intermittent fever. He had been well until September 14, 1943, when there was onset of headache and malaise. He felt feverish, and his temperature was 99.5°F. He was unusually tired and later developed a moderate degree of prostration. The past history was unimportant.

Physical examination was essentially negative throughout the first week of illness. The red-cell count was 4,490,000 and the hemoglobin 90 per cent. The white-cell count ranged from 6500 on September 17 to 18,000 on September 27, with differential counts as follows: on September 17, 57 per cent neutrophils, 35 per cent lymphocytes, 7 per cent monocytes and 1 per cent basophils; on September 27, 20 per cent neutrophils, 77 per cent lymphocytes and 3 per cent monocytes. Agglutination reactions for undulant fever and typhus fever were negative. On September 22, the Widal reaction was weakly positive in a dilution of 1:40. On the same day the heterophile antibody reaction was positive in a titer of 1:128. A stool culture on September 27 was negative for the typhoid bacillus. Urinalysis was negative.

The severe headache was a particularly troublesome symptom, although large doses of aspirin gave some relief. Sulfadiazine was administered for 4 days without any apparent response. Postcervical lymphadenopathy was noted on the 9th day of the illness, when the temperature had become practically normal. At the same time the spleen became palpable. The temperature was 99.8°F on September 25, and became normal thereafter. Except for a feeling of tiredness that persisted for 1 month, recovery was uneventful.

Diagnosis: infectious mononucleosis.

CASE 2. R. B., a 30-year-old machinist, was admitted to a hospital on May 25, 1943, with chief complaints of severe headache and fever. Except for an eruption in the region of both ankles he had been well until May 20, when he developed sore throat and fever. He believed that his symptoms were related to the rash on the ankles. Several days later he began having severe headaches. When the temperature and sore throat persisted, hospitalization was advised. The past history was not important except that the patient's legs were constantly exposed to cutting oils absorbed by his trousers.

On admission the temperature was 101°F. Except for an eruption on both ankles, the physical examination was not remarkable. The red-cell count was 4,600,000, the hemoglobin 87 per cent, and the white-cell count 7800, with 45 per cent neutrophils and 55 per cent lymphocytes. A blood culture on June 2 was negative. Urinalysis was negative. The agglutination tests on June 5 were as follows: typhoid and undulant-fever reactions, negative; heterophile antibody reaction, positive in a titer of 1:1024.

Until June 6 the temperature ranged from 98.8 to 103°F. The sore throat became worse following admission and the headaches were unusually severe. Occasionally there were chills and profuse sweats. On May 31, the lesions on the legs had healed completely but the headache persisted. On the same day there occurred several momentary faints. Lumbar puncture, performed because of the severe headache, backache and faints, revealed a clear, colorless fluid, with an initial pressure equivalent to 580 mm. of water, a cell count of 12 lymphocytes, a total protein of 57 mg. per 100 cc., a positive Pandy reaction and a normal sugar level. Following this lumbar puncture there was marked relief from symptoms. The temperature subsided within a few days, and the patient made an uneventful recovery. On June 1, enlargement of the posterior cervical lymph nodes was discovered.

Diagnosis: infectious mononucleosis and occupational dermatitis of both ankles.

CASE 3. L. L., a 34-year-old married man, was admitted to a hospital on October 7, 1943, with a chief complaint of severe abdominal cramps. He had been well until three days prior to admission, when there were intermittent attacks of severe, cramplike pain in the lower abdomen, during which the patient felt nauseated but did not vomit. There were no other intestinal symptoms. When the attacks had persisted for 3 days, hospitalization was advised for further study. There was no history of any similar illness in the past.

On admission the temperature was 98.8°F., the pulse 90, and the respirations 20. Except for tenderness over the lower abdomen, the general physical examination was negative. The red-cell count was 4,900,000 and the hemoglobin 92 per cent. The white-cell count ranged from 16,300 on October 7 to 22,900 on October 14, with differential counts as follows: on October 7, 26 per cent neutrophils, 67 per cent small lymphocytes and 7 per cent large lymphocytes; on October 14, 23 per cent neutrophils, 52 per cent small lymphocytes and 25 per cent large lymphocytes; on October 21, 22 per cent neutrophils, 60 per cent small lymphocytes and 18 per cent large lymphocytes. Agglutination reactions using typhoid and brucella organisms were negative on October 8 and 9. The heterophile antibody reaction on October 9 was positive in a titer of 1:512. Urinalysis was negative.

The abdominal cramps persisted for 48 hours after admission and subsided with symptomatic treatment. On the 2nd hospital day, the temperature began to rise and the patient developed a low-grade fever that persisted for two weeks, the temperature ranging from 98.8 to 100°F. During that time he lost considerable strength and felt extremely tired. On the 8th day, enlargement of the left posterior cervical nodes was noted, and the swelling persisted throughout the hospital stay. The patient was discharged on the 18th day after having been afebrile for 3 days. The feeling of tiredness persisted for several weeks after discharge.

Diagnosis: infectious mononucleosis.

CASE 4. J. O., a 44-year-old sheet-metal worker, was admitted to a hospital on March 28, 1943, with chief complaints of fever and malaise. He had been fairly well until March 21, when there was onset of malaise and anorexia. He tempted self-medication with proprietary drugs and bed rest, but without relief. He then became aware of chills, sweats and afternoon sweats. Within the next few days he began having severe occipital headaches. He consulted

his physician, who found that the temperature was 101°F. There was no cough or other symptoms of upper respiratory infection. The past history was not important except that the patient was employed as a sheet-metal worker in a painting plant. Although he did not handle meat products, he often repaired metal runways used in the processing of products.

On admission, the temperature was 101°F., the pulse 100, and the respirations 20. Physical examination was negative. The red-cell count was 4,200,000, the hemoglobin 81 per cent, and the white-cell count 10,400, with 76 per cent neutrophils, 23 per cent lymphocytes and 1 per cent eosinophils. Urinalysis was negative. A blood Hinton test was negative. Agglutination tests on April 2 were reported as follows: typhoid and paratyphoid reactions, negative; undulant-fever reaction, positive in a titer of 1:405. X-ray examination of the chest on April 2 was negative.

The temperature remained elevated for 3 weeks after admission. During the 1st week it averaged 101°F. during the afternoon and evening and was considerably lower in the morning. During the 2nd and 3rd weeks the patient was afebrile in the morning, and the afternoon and evening temperatures varied from 99.6 to 102°F. There was change in the physical findings. Recovery was uneven following subsidence of the fever.

Diagnosis: undulant fever.

CASE 5. R. L., a 5-year-old boy, was admitted to a hospital on April 3, 1935, with chief complaints of fever and malaise. He had been well until 8 days prior to admission, when he became listless and fretful. There was general malaise and anorexia. The family physician found that the rectal temperature was elevated, varying between 99 and 103°F. Since there was no improvement after 4 days, hospitalization was advised. The past history revealed the usual childhood diseases. For several months the patient had been drinking raw milk. Adjoining the property on which he lived, there was a large piggery, but no history of contact with pigs could be established.

On admission on January 25, the temperature was 105°F., the pulse 120, and the respirations 36. The patient appeared pale and listless and was quite ill. The significant findings of the physical examination were marked splenomegaly, hepatomegaly and engorgement of the superficial vessels of the abdomen. The red-cell count was 3,640,000 and the hemoglobin 78 per cent. The white-cell count gradually rose from 3400 on January 21 to 5500 on February 27, with differential counts as follows: on January 21, 46 per cent neutrophils, 46 per cent lymphocytes, 6 per cent monocytes and 2 per cent eosinophils; on January 27, 36 per cent neutrophils, 52 per cent lymphocytes, 10 per cent monocytes and 2 per cent basophils; on February 3, 44 per cent neutrophils, 44 per cent lymphocytes and 5 per cent monocytes. Urinalysis was essentially negative. A blood Hinton test was negative. Agglutination tests on January 23 were as follows: typhoid and typhus reactions, negative; undulant-fever reaction positive in a dilution of 1:32,805 and partially positive one of 1:98,415. On February 15 and February 20, blood cultures revealed *Br. suis*. On January 21, x-ray examination of the chest was negative.

The temperature remained extremely high during the first 2 weeks of the illness. On January 28, therapy with a brucella vaccine was instituted, and there was a marked rise in temperature following each dose. On February 7, there was some diminution in the size of the liver and spleen, although the patient still appeared quite ill. Late in February, except for the febrile response following the administration of vaccine, the temperature became normal. Later, when the vaccine was discontinued, the temperature remained normal. On March 12, there was a recurrence of fever, and this persisted until March 20. Thereafter, except for an occasional rise to 100°F. during the afternoon and evening, the patient remained afebrile. There was an uneventful recovery.

Diagnosis: undulant fever.

CASE 6. R. H., a 27-year-old veterinarian, consulted his physician in December, 1939, with complaints of weakness and swelling of the scrotum. For several days he had tired easily, and this was followed by a painful swelling of the scrotum. The physician found that the temperature was 102°F. There was no history of urethral discharge preceding the onset of the present illness.

Physical examination revealed swelling and redness of the rotum, most noticeable on the left side, where there was marked tenderness. The epididymis on the left was enlarged and tender. There was only slight involvement of the testis. The examination was otherwise negative. During the preceding month, the patient had extracted manually several stained bovine placentas.

The swelling subsided after 7 days, only to recur during the following week, when it lasted for 3 days. The temperature remained elevated for 2 weeks. Thereafter, although there was no recurrence of acute symptoms, the patient tired easily and was unable to exert himself as much as previously. This condition persisted for several months. In March, 1940, the agglutination reaction for undulant fever was positive in a dilution of 1:405. There had been some improvement in the patient's condition, but he had not recovered all his former vitality.

Diagnosis: undulant fever, with epididymitis.

DISCUSSION

Case 1 is presented as a typical example of infectious mononucleosis. Except for the absence of sore throat, which is a fairly common finding, the symptomatology and clinical course are characteristic. Headache is a frequent complaint. In Case 2, the severe persistent headache, faints and spinal-fluid findings suggested involvement of the central nervous system.

Thelander and Shaw¹⁵ have expressed the opinion that the headache that occurs in most patients with infectious mononucleosis indicates cerebral involvement. In some cases there is evidence of encephalitis, with difficulty in speech and mental confusion. Signs of meningeal irritation may be encountered, with a moderate increase of cells in the spinal fluid. Cell counts in such cases usually average about 50 to 80 cells per cubic centimeter, although higher counts may occur. The spinal-fluid pressure may be elevated, and the total protein increased.

Landes, Reich and Perlow¹⁶ reported a case with manifestations of the central nervous system in which lymphadenopathy and splenomegaly did not appear until twenty-two days after the onset. The authors suggest that the heterophile antibody reaction should be performed in all cases of acute infection with obscure cerebral symptoms.

The third case of infectious mononucleosis (Case 3) is presented because of the prominence of gastrointestinal symptoms, which may mask the underlying etiology. Such patients have undergone operation with a mistaken diagnosis of appendicitis.¹⁷ The abdominal symptoms are attributed to enlarged mesenteric nodes. This type of case may present roentgenographic findings that are helpful in diagnosis.¹⁸

Case 4 is an example of the usual clinical variety of undulant fever prevalent in Massachusetts. Most of the cases are extremely mild. Characteristically, the patient feels fairly well in the morning, and as the fever rises in the afternoon and evening the symptoms become more marked. The physical findings are usually insignificant.

Simpson¹⁹ points out that the name "undulant fever" is inadequate. This term implies one or more

recurrences of fever with quiescent intervals. Such recurrences, however, are found only in the exceptional case. Most patients exhibit a single bout of fever lasting from a few days to several weeks or months, following which recovery is uneventful.

Case 5 is of extreme interest and represents perhaps the severest form of undulant fever. High fever, marked enlargement of the liver and spleen, prostration, leukopenia with lymphocytosis, intermittent fever and a protracted course are rarely combined in the same case. The agglutination reaction was positive in an unusually high titer early in the course. Undulant fever rarely occurs among children. This patient, five years of age, is the youngest thus far reported in Massachusetts.

Since 1930, when undulant fever became a reportable disease in Massachusetts, only 1 case of brucellosis complicated by epididymitis or orchitis (Case 6) has been recorded. Simpson¹⁹ states that brucella organisms may exhibit a predilection for the genital tract of human beings as well as of cattle, and that orchitis occurs in 10 per cent of the cases of undulant fever. Orr²⁰ reported this complication in 8 per cent of his cases. Occasionally orchitis or epididymitis is the first and only sign of this disease.²¹ This condition may be confused with tuberculous epididymitis. In rural communities where undulant fever due to ingestion of raw milk is more frequent than in urban areas, this complication may occur more frequently than is commonly supposed.

Although some cases of infectious mononucleosis and undulant fever are striking in their manifestations, comparison of Case 1 and Case 4, each characteristic of the usually encountered clinical variety of the respective disease, demonstrates their marked similarity. Since infectious mononucleosis is not a reportable disease, no figures concerning its incidence are available. Our experience suggests, however, that it is a fairly common infection of young adults. For this reason, an awareness of the possibility of confusing these infections may prevent many errors in diagnosis.

SUMMARY

Experience with reported cases of undulant fever has demonstrated that this disease may be readily confused with infectious mononucleosis.

The heterophile antibody reaction, performed routinely on 1000 consecutive blood serums submitted by physicians for undulant fever agglutination, revealed 13 cases of infectious mononucleosis. Although these specimens were submitted specifically for undulant fever, only 36 were positive for that disease.

In urban areas, except for cases contracted elsewhere, undulant fever is essentially an occupational disease.

Five cases of undulant fever occurred among machinists and metal workers handling materials

CASE 2. R. B., a 30-year-old machinist, was admitted to a hospital on May 25, 1943, with chief complaints of severe headache and fever. Except for an eruption in the region of both ankles he had been well until May 20, when he developed sore throat and fever. He believed that his symptoms were related to the rash on the ankles. Several days later he began having severe headaches. When the temperature and sore throat persisted, hospitalization was advised. The past history was not important except that the patient's legs were constantly exposed to cutting oils absorbed by his trousers.

On admission the temperature was 101°F. Except for an eruption on both ankles, the physical examination was not remarkable. The red-cell count was 4,600,000, the hemoglobin 87 per cent, and the white-cell count 7800, with 45 per cent neutrophils and 55 per cent lymphocytes. A blood culture on June 2 was negative. Urinalysis was negative. The agglutination tests on June 5 were as follows: typhoid and undulant-fever reactions, negative; heterophile antibody reaction, positive in a titer of 1:1024.

Until June 6 the temperature ranged from 98.8 to 103°F. The sore throat became worse following admission and the headaches were unusually severe. Occasionally there were chills and profuse sweats. On May 31, the lesions on the legs had healed completely but the headache persisted. On the same day there occurred several momentary faints. Lumbar puncture, performed because of the severe headache, backache and faints, revealed a clear, colorless fluid, with an initial pressure equivalent to 580 mm. of water, a cell count of 12 lymphocytes, a total protein of 57 mg. per 100 cc., a positive Pandy reaction and a normal sugar level. Following this lumbar puncture there was marked relief from symptoms. The temperature subsided within a few days, and the patient made an uneventful recovery. On June 1, enlargement of the posterior cervical lymph nodes was discovered.

Diagnosis: infectious mononucleosis and occupational dermatitis of both ankles.

CASE 3. L. L., a 34-year-old married man, was admitted to a hospital on October 7, 1943, with a chief complaint of severe abdominal cramps. He had been well until three days prior to admission, when there were intermittent attacks of severe, cramplike pain in the lower abdomen, during which the patient felt nauseated but did not vomit. There were no other intestinal symptoms. When the attacks had persisted for 3 days, hospitalization was advised for further study. There was no history of any similar illness in the past.

On admission the temperature was 98.8°F., the pulse 90, and the respirations 20. Except for tenderness over the lower abdomen, the general physical examination was negative. The red-cell count was 4,900,000 and the hemoglobin 92 per cent. The white-cell count ranged from 16,300 on October 7 to 22,900 on October 14, with differential counts as follows: on October 7, 26 per cent neutrophils, 67 per cent small lymphocytes and 7 per cent large lymphocytes; on October 14, 23 per cent neutrophils, 52 per cent small lymphocytes and 25 per cent large lymphocytes; on October 21, 22 per cent neutrophils, 60 per cent small lymphocytes and 18 per cent large lymphocytes. Agglutination reactions using typhoid and brucella organisms were negative on October 8 and 9. The heterophile antibody reaction on October 9 was positive in a titer of 1:512. Urinalysis was negative.

The abdominal cramps persisted for 48 hours after admission and subsided with symptomatic treatment. On the 2nd hospital day, the temperature began to rise and the patient developed a low-grade fever that persisted for two weeks, the temperature ranging from 98.8 to 100°F. During that time he lost considerable strength and felt extremely tired. On the 8th day, enlargement of the left posterior cervical nodes was noted, and the swelling persisted throughout the hospital stay. The patient was discharged on the 18th day after having been afebrile for 3 days. The feeling of tiredness persisted for several weeks after discharge.

Diagnosis: infectious mononucleosis.

CASE 4. J. O., a 44-year-old sheet-metal worker, was admitted to a hospital on March 28, 1943, with chief complaints of fever and malaise. He had been fairly well until March 21, when there was onset of malaise and anorexia. He tempted self-medication with proprietary drugs and bed rest, but without relief. He then became aware of chilly sensations and afternoon sweats. Within the next few days he began having severe occipital headaches. He consulted

his physician, who found that the temperature was 101°F. There was no cough or other symptoms of upper respiratory infection. The past history was not important except that the patient was employed as a sheet-metal worker in a firing plant. Although he did not handle meat products, often repaired metal runways used in the processing of products.

On admission, the temperature was 101°F., the pulse and the respirations 20. Physical examination was negative. The red-cell count was 4,200,000, the hemoglobin 81 per cent, and the white-cell count 10,400, with 76 per cent neutrophils, 23 per cent lymphocytes and 1 per cent eosinophils. Urinalysis was negative. A blood Hinton test was negative. Agglutination tests on April 2 were reported as follows: typhoid and paratyphoid reactions, negative; undulant-fever reaction, positive in a titer of 1:405. X-ray examination of the chest on April 2 was negative.

The temperature remained elevated for 3 weeks after admission. During the 1st week it averaged 101°F. during the afternoon and evening and was considerably lower in the morning. During the 2nd and 3rd weeks the patient was afebrile in the morning, and the afternoon and evening temperatures varied from 99.6 to 102°F. There was a change in the physical findings. Recovery was uneventful following subsidence of the fever.

Diagnosis: undulant fever.

CASE 5. R. L., a 5-year-old boy, was admitted to a hospital on April 3, 1935, with chief complaints of fever and malaise. He had been well until 8 days prior to admission, when he became listless and fretful. There was general malaise, anorexia. The family physician found that the rectal temperature was elevated, varying between 99 and 103°F. Since there was no improvement after 4 days, hospitalization was advised. The past history revealed the usual childhood diseases. For several months the patient had been drinking raw milk. Adjoining the property on which he lived, there was a large piggery, but no history of contact with pigs could be established.

On admission on January 25, the temperature was 105°F., the pulse 120, and the respirations 36. The patient appeared pale and listless and was quite ill. The significant findings on the physical examination were marked splenomegaly, hepatomegaly and engorgement of the superficial vessels of the abdomen. The red-cell count was 3,640,000 and the hemoglobin 78 per cent. The white-cell count gradually rose from 3400 on January 21 to 5500 on February 27, with differential counts as follows: on January 21, 46 per cent neutrophils, 46 per cent lymphocytes, 6 per cent monocytes and 2 per cent eosinophils; on January 27, 36 per cent neutrophils, 52 per cent lymphocytes, 10 per cent monocytes and 2 per cent basophils; on February 3, 44 per cent neutrophils, 51 per cent lymphocytes and 5 per cent monocytes. Urinalysis was essentially negative. A blood Hinton test was negative. Agglutination tests on January 23 were as follows: typhoid and typhus reactions, negative; undulant-fever reaction, positive in a dilution of 1:32,805 and partially positive in one of 1:98,415. On February 15 and February 20, blood cultures revealed *Br. suis*. On January 21, x-ray examination of the chest was negative.

The temperature remained extremely high during the first 2 weeks of the illness. On January 28, therapy with a brucella vaccine was instituted, and there was a marked rise in temperature following each dose. On February 7, there was some diminution in the size of the liver and spleen, although the patient still appeared quite ill. Late in February, except for the febrile response following the administration of vaccine, the temperature became normal. Later, when the vaccine was discontinued, the temperature remained normal. On March 12, there was a recurrence of fever, and this persisted until March 20. Thereafter, except for an occasional rise to 100°F. during the afternoon and evening, the patient remained afebrile. There was an uneventful recovery.

Diagnosis: undulant fever.

CASE 6. R. H., a 27-year-old veterinarian, consulted his physician in December, 1939, with complaints of weakness and swelling of the scrotum. For several days he had tired easily, and this was followed by a painful swelling of the scrotum. The physician found that the temperature was 102°F. There was no history of urethral discharge preceding the onset of the present illness.

Physical examination revealed swelling and redness of the rotum, most noticeable on the left side, where there was marked tenderness. The epididymis on the left was enlarged and tender. There was only slight involvement of the testis. The examination was otherwise negative. During the preceding month, the patient had extracted manually several retained bovine placentas.

The swelling subsided after 7 days, only to recur during the following week, when it lasted for 3 days. The temperature remained elevated for 2 weeks. Thereafter, although there was no recurrence of acute symptoms, the patient tired easily and was unable to exert himself as much as previously. This condition persisted for several months. In March, 1940, the agglutination reaction for undulant fever was positive in a dilution of 1:405. There had been some improvement in the patient's condition, but he had not recovered all his former vitality.

Diagnosis: undulant fever, with epididymitis.

DISCUSSION

Case 1 is presented as a typical example of infectious mononucleosis. Except for the absence of sore throat, which is a fairly common finding, the symptomatology and clinical course are characteristic. Headache is a frequent complaint. In Case 2, the severe persistent headache, faints and spinal-fluid findings suggested involvement of the central nervous system.

Thelander and Shaw¹⁵ have expressed the opinion that the headache that occurs in most patients with infectious mononucleosis indicates cerebral involvement. In some cases there is evidence of encephalitis, with difficulty in speech and mental confusion. Signs of meningeal irritation may be encountered, with a moderate increase of cells in the spinal fluid. Cell counts in such cases usually average about 50 to 80 cells per cubic centimeter, although higher counts may occur. The spinal-fluid pressure may be elevated, and the total protein increased.

Landes, Reich and Perlow¹⁶ reported a case with manifestations of the central nervous system in which lymphadenopathy and splenomegaly did not appear until twenty-two days after the onset. The authors suggest that the heterophile antibody reaction should be performed in all cases of acute infection with obscure cerebral symptoms.

The third case of infectious mononucleosis (Case 3) is presented because of the prominence of gastrointestinal symptoms, which may mask the underlying etiology. Such patients have undergone operation with a mistaken diagnosis of appendicitis.¹⁷ The abdominal symptoms are attributed to enlarged mesenteric nodes. This type of case may present roentgenographic findings that are helpful in diagnosis.¹⁸

Case 4 is an example of the usual clinical variety of undulant fever prevalent in Massachusetts. Most of the cases are extremely mild. Characteristically, the patient feels fairly well in the morning, and as the fever rises in the afternoon and evening the symptoms become more marked. The physical findings are usually insignificant.

Simpson¹⁹ points out that the name "undulant fever" is inadequate. This term implies one or more

recurrences of fever with quiescent intervals. Such recurrences, however, are found only in the exceptional case. Most patients exhibit a single bout of fever lasting from a few days to several weeks or months, following which recovery is uneventful.

Case 5 is of extreme interest and represents perhaps the severest form of undulant fever. High fever, marked enlargement of the liver and spleen, prostration, leukopenia with lymphocytosis, intermittent fever and a protracted course are rarely combined in the same case. The agglutination reaction was positive in an unusually high titer early in the course. Undulant fever rarely occurs among children. This patient, five years of age, is the youngest thus far reported in Massachusetts.

Since 1930, when undulant fever became a reportable disease in Massachusetts, only 1 case of brucellosis complicated by epididymitis or orchitis (Case 6) has been recorded. Simpson¹⁹ states that brucella organisms may exhibit a predilection for the genital tract of human beings as well as of cattle, and that orchitis occurs in 10 per cent of the cases of undulant fever. Orr²⁰ reported this complication in 8 per cent of his cases. Occasionally orchitis or epididymitis is the first and only sign of this disease.²¹ This condition may be confused with tuberculous epididymitis. In rural communities where undulant fever due to ingestion of raw milk is more frequent than in urban areas, this complication may occur more frequently than is commonly supposed.

Although some cases of infectious mononucleosis and undulant fever are striking in their manifestations, comparison of Case 1 and Case 4, each characteristic of the usually encountered clinical variety of the respective disease, demonstrates their marked similarity. Since infectious mononucleosis is not a reportable disease, no figures concerning its incidence are available. Our experience suggests, however, that it is a fairly common infection of young adults. For this reason, an awareness of the possibility of confusing these infections may prevent many errors in diagnosis.

SUMMARY

Experience with reported cases of undulant fever has demonstrated that this disease may be readily confused with infectious mononucleosis.

The heterophile antibody reaction, performed routinely on 1000 consecutive blood serums submitted by physicians for undulant fever agglutination, revealed 13 cases of infectious mononucleosis. Although these specimens were submitted specifically for undulant fever, only 36 were positive for that disease.

In urban areas, except for cases contracted elsewhere, undulant fever is essentially an occupational disease.

Five cases of undulant fever occurred among machinists and metal workers handling materials

CASE 2. R. B., a 30-year-old machinist, was admitted to a hospital on May 25, 1943, with chief complaints of severe headache and fever. Except for an eruption in the region of both ankles he had been well until May 20, when he developed sore throat and fever. He believed that his symptoms were related to the rash on the ankles. Several days later he began having severe headaches. When the temperature and sore throat persisted, hospitalization was advised. The past history was not important except that the patient's legs were constantly exposed to cutting oils absorbed by his trousers.

On admission the temperature was 101°F. Except for an eruption on both ankles, the physical examination was not remarkable. The red-cell count was 4,600,000, the hemoglobin 87 per cent, and the white-cell count 7800, with 45 per cent neutrophils and 55 per cent lymphocytes. A blood culture on June 2 was negative. Urinalysis was negative. The agglutination tests on June 5 were as follows: typhoid and undulant-fever reactions, negative; heterophile antibody reaction, positive in a titer of 1:1024.

Until June 6 the temperature ranged from 98.8 to 103°F. The sore throat became worse following admission and the headaches were unusually severe. Occasionally there were chills and profuse sweats. On May 31, the lesions on the legs had healed completely but the headache persisted. On the same day there occurred several momentary faints. Lumbar puncture, performed because of the severe headache, backache and faints, revealed a clear, colorless fluid, with an initial pressure equivalent to 580 mm. of water, a cell count of 12 lymphocytes, a total protein of 57 mg. per 100 cc., a positive Pandy reaction and a normal sugar level. Following this lumbar puncture there was marked relief from symptoms. The temperature subsided within a few days, and the patient made an uneventful recovery. On June 1, enlargement of the posterior cervical lymph nodes was discovered.

Diagnosis: infectious mononucleosis and occupational dermatitis of both ankles.

CASE 3. L. L., a 34-year-old married man, was admitted to a hospital on October 7, 1943, with a chief complaint of severe abdominal cramps. He had been well until three days prior to admission, when there were intermittent attacks of severe, cramplike pain in the lower abdomen, during which the patient felt nauseated but did not vomit. There were no other intestinal symptoms. When the attacks had persisted for 3 days, hospitalization was advised for further study. There was no history of any similar illness in the past.

On admission the temperature was 98.8°F., the pulse 90, and the respirations 20. Except for tenderness over the lower abdomen, the general physical examination was negative. The red-cell count was 4,900,000 and the hemoglobin 92 per cent. The white-cell count ranged from 16,300 on October 7 to 22,900 on October 14, with differential counts as follows: on October 7, 26 per cent neutrophils, 67 per cent small lymphocytes and 7 per cent large lymphocytes; on October 14, 23 per cent neutrophils, 52 per cent small lymphocytes and 25 per cent large lymphocytes; on October 21, 22 per cent neutrophils, 60 per cent small lymphocytes and 18 per cent large lymphocytes. Agglutination reactions using typhoid and brucella organisms were negative on October 8 and 9. The heterophile antibody reaction on October 9 was positive in a titer of 1:512. Urinalysis was negative.

The abdominal cramps persisted for 48 hours after admission and subsided with symptomatic treatment. On the 2nd hospital day, the temperature began to rise and the patient developed a low-grade fever that persisted for two weeks, the temperature ranging from 98.8 to 100°F. During that time he lost considerable strength and felt extremely tired. On the 8th day, enlargement of the left posterior cervical nodes was noted, and the swelling persisted throughout the hospital stay. The patient was discharged on the 18th day after having been afebrile for 3 days. The feeling of tiredness persisted for several weeks after discharge.

Diagnosis: infectious mononucleosis.

CASE 4. J. O., a 44-year-old sheet-metal worker, was admitted to a hospital on March 28, 1943, with chief complaints of fever and malaise. He had been fairly well until March 21, when there was onset of malaise and anorexia. He tempted self-medication with proprietary drugs and bed rest, but without relief. He then became aware of chills, sweats and afternoon sweats. Within the next few days he began having severe occipital headaches. He consulted

his physician, who found that the temperature was 101°F. There was no cough or other symptoms of upper respiratory infection. The past history was not important except that the patient was employed as a sheet-metal worker in a tinning plant. Although he did not handle meat products, often repaired metal runways used in the processing of products.

On admission, the temperature was 101°F., the pulse 100 and the respirations 20. Physical examination was negative. The red-cell count was 4,200,000, the hemoglobin 81 per cent, and the white-cell count 10,400, with 76 per cent neutrophils, 23 per cent lymphocytes and 1 per cent eosinophils. Urinalysis was negative. A blood Hinton test was negative. Agglutination tests on April 2 were reported as follows: typhoid and paratyphoid reactions, negative; undulant-fever reaction, positive in a titer of 1:405. X-ray examination of the chest on April 2 was negative.

The temperature remained elevated for 3 weeks after admission. During the 1st week it averaged 101°F. during the afternoon and evening and was considerably lower in the morning. During the 2nd and 3rd weeks the patient was afebrile in the morning, and the afternoon and evening temperatures varied from 99.6 to 102°F. There was no change in the physical findings. Recovery was uneventful following subsidence of the fever.

Diagnosis: undulant fever.

CASE 5. R. L., a 5-year-old boy, was admitted to a hospital on April 3, 1935, with chief complaints of fever and malaise. He had been well until 8 days prior to admission, when he became listless and fretful. There was general malaise and anorexia. The family physician found that the rectal temperature was elevated, varying between 99 and 103°F. Since there was no improvement after 4 days, hospitalization was advised. The past history revealed the usual childhood diseases. For several months the patient had been drinking raw milk. Adjoining the property on which he lived, there was a large piggery, but no history of contact with pigs could be established.

On admission on January 25, the temperature was 105°F., the pulse 120, and the respirations 36. The patient appeared pale and listless and was quite ill. The significant findings in the physical examination were marked splenomegaly, hepatomegaly and engorgement of the superficial vessels of the abdomen. The red-cell count was 3,640,000 and the hemoglobin 78 per cent. The white-cell count gradually rose from 3400 on January 21 to 5500 on February 27, with differential counts as follows: on January 21, 46 per cent neutrophils, 46 per cent lymphocytes, 6 per cent monocytes and 2 per cent eosinophils; on January 27, 36 per cent neutrophils, 52 per cent lymphocytes, 10 per cent monocytes and 2 per cent basophils; on February 3, 44 per cent neutrophils, 51 per cent lymphocytes and 5 per cent monocytes. Urinalysis was essentially negative. A blood Hinton test was negative. Agglutination tests on January 23 were as follows: typhoid and typhus reactions, negative; undulant-fever reaction, positive in a dilution of 1:32,805 and partially positive in one of 1:98,415. On February 15 and February 20, blood cultures revealed *Br. suis*. On January 21, x-ray examination of the chest was negative.

The temperature remained extremely high during the first 2 weeks of the illness. On January 28, therapy with a brucella vaccine was instituted, and there was a marked rise in temperature following each dose. On February 7, there was some diminution in the size of the liver and spleen, although the patient still appeared quite ill. Late in February, except for the febrile response following the administration of vaccine, the temperature became normal. Later, when the vaccine was discontinued, the temperature remained normal. On March 12, there was a recurrence of fever, and this persisted until March 20. Thereafter, except for an occasional rise to 100°F. during the afternoon and evening, the patient remained afebrile. There was an uneventful recovery.

Diagnosis: undulant fever.

CASE 6. R. H., a 27-year-old veterinarian, consulted his physician in December, 1939, with complaints of weakness and swelling of the scrotum. For several days he had tired easily, and this was followed by a painful swelling of the scrotum. The physician found that the temperature was 102°F. There was no history of urethral discharge preceding the onset of the present illness.

Physical examination revealed swelling and redness of the rotum, most noticeable on the left side, where there was marked tenderness. The epididymis on the left was enlarged and tender. There was only slight involvement of the testis. The examination was otherwise negative. During the preceding month, the patient had extracted manually several stained bovine placentas.

The swelling subsided after 7 days, only to recur during the following week, when it lasted for 3 days. The temperature remained elevated for 2 weeks. Thereafter, although there was no recurrence of acute symptoms, the patient tired easily and was unable to exert himself as much as previously. This condition persisted for several months. In March, 1940, the agglutination reaction for undulant fever was positive in a dilution of 1:405. There had been some improvement in the patient's condition, but he had not recovered all his former vitality.

Diagnosis: undulant fever, with epididymitis.

DISCUSSION

Case 1 is presented as a typical example of infectious mononucleosis. Except for the absence of sore throat, which is a fairly common finding, the symptomatology and clinical course are characteristic. Headache is a frequent complaint. In Case 2, the severe persistent headache, faints and spinal-fluid findings suggested involvement of the central nervous system.

Thelander and Shaw¹⁵ have expressed the opinion that the headache that occurs in most patients with infectious mononucleosis indicates cerebral involvement. In some cases there is evidence of encephalitis, with difficulty in speech and mental confusion. Signs of meningeal irritation may be encountered, with a moderate increase of cells in the spinal fluid. Cell counts in such cases usually average about 50 to 80 cells per cubic centimeter, although higher counts may occur. The spinal-fluid pressure may be elevated, and the total protein increased.

Landes, Reich and Perlow¹⁶ reported a case with manifestations of the central nervous system in which lymphadenopathy and splenomegaly did not appear until twenty-two days after the onset. The authors suggest that the heterophile antibody reaction should be performed in all cases of acute infection with obscure cerebral symptoms.

The third case of infectious mononucleosis (Case 3) is presented because of the prominence of gastrointestinal symptoms, which may mask the underlying etiology. Such patients have undergone operation with a mistaken diagnosis of appendicitis.¹⁷ The abdominal symptoms are attributed to enlarged mesenteric nodes. This type of case may present roentgenographic findings that are helpful in diagnosis.¹⁸

Case 4 is an example of the usual clinical variety of undulant fever prevalent in Massachusetts. Most of the cases are extremely mild. Characteristically, the patient feels fairly well in the morning, and as the fever rises in the afternoon and evening the symptoms become more marked. The physical findings are usually insignificant.

Simpson¹⁹ points out that the name "undulant fever" is inadequate. This term implies one or more

recurrences of fever with quiescent intervals. Such recurrences, however, are found only in the exceptional case. Most patients exhibit a single bout of fever lasting from a few days to several weeks or months, following which recovery is uneventful.

Case 5 is of extreme interest and represents perhaps the severest form of undulant fever. High fever, marked enlargement of the liver and spleen, prostration, leukopenia with lymphocytosis, intermittent fever and a protracted course are rarely combined in the same case. The agglutination reaction was positive in an unusually high titer early in the course. Undulant fever rarely occurs among children. This patient, five years of age, is the youngest thus far reported in Massachusetts.

Since 1930, when undulant fever became a reportable disease in Massachusetts, only 1 case of brucellosis complicated by epididymitis or orchitis (Case 6) has been recorded. Simpson¹⁹ states that brucella organisms may exhibit a predilection for the genital tract of human beings as well as of cattle, and that orchitis occurs in 10 per cent of the cases of undulant fever. Orr²⁰ reported this complication in 8 per cent of his cases. Occasionally orchitis or epididymitis is the first and only sign of this disease.²¹ This condition may be confused with tuberculous epididymitis. In rural communities where undulant fever due to ingestion of raw milk is more frequent than in urban areas, this complication may occur more frequently than is commonly supposed.

Although some cases of infectious mononucleosis and undulant fever are striking in their manifestations, comparison of Case 1 and Case 4, each characteristic of the usually encountered clinical variety of the respective disease, demonstrates their marked similarity. Since infectious mononucleosis is not a reportable disease, no figures concerning its incidence are available. Our experience suggests, however, that it is a fairly common infection of young adults. For this reason, an awareness of the possibility of confusing these infections may prevent many errors in diagnosis.

SUMMARY

Experience with reported cases of undulant fever has demonstrated that this disease may be readily confused with infectious mononucleosis.

The heterophile antibody reaction, performed routinely on 1000 consecutive blood serums submitted by physicians for undulant fever agglutination, revealed 13 cases of infectious mononucleosis. Although these specimens were submitted specifically for undulant fever, only 36 were positive for that disease.

In urban areas, except for cases contracted elsewhere, undulant fever is essentially an occupational disease.

Five cases of undulant fever occurred among machinists and metal workers handling materials

CASE 2. R. B., a 30-year-old machinist, was admitted to a hospital on May 25, 1943, with chief complaints of severe headache and fever. Except for an eruption in the region of both ankles he had been well until May 20, when he developed sore throat and fever. He believed that his symptoms were related to the rash on the ankles. Several days later he began having severe headaches. When the temperature and sore throat persisted, hospitalization was advised. The past history was not important except that the patient's legs were constantly exposed to cutting oils absorbed by his trousers.

On admission the temperature was 101°F. Except for an eruption on both ankles, the physical examination was not remarkable. The red-cell count was 4,600,000, the hemoglobin 87 per cent, and the white-cell count 7800, with 45 per cent neutrophils and 55 per cent lymphocytes. A blood culture on June 2 was negative. Urinalysis was negative. The agglutination tests on June 5 were as follows: typhoid and undulant-fever reactions, negative; heterophile antibody reaction, positive in a titer of 1:1024.

Until June 6 the temperature ranged from 98.8 to 103°F. The sore throat became worse following admission and the headaches were unusually severe. Occasionally there were chills and profuse sweats. On May 31, the lesions on the legs had healed completely but the headache persisted. On the same day there occurred several momentary faints. Lumbar puncture, performed because of the severe headache, backache and faints, revealed a clear, colorless fluid, with an initial pressure equivalent to 580 mm. of water, a cell count of 12 lymphocytes, a total protein of 57 mg. per 100 cc., a positive Pandy reaction and a normal sugar level. Following this lumbar puncture there was marked relief from symptoms. The temperature subsided within a few days, and the patient made an uneventful recovery. On June 1, enlargement of the posterior cervical lymph nodes was discovered.

Diagnosis: infectious mononucleosis and occupational dermatitis of both ankles.

CASE 3. L. L., a 34-year-old married man, was admitted to a hospital on October 7, 1943, with a chief complaint of severe abdominal cramps. He had been well until three days prior to admission, when there were intermittent attacks of severe, cramplike pain in the lower abdomen, during which the patient felt nauseated but did not vomit. There were no other intestinal symptoms. When the attacks had persisted for 3 days, hospitalization was advised for further study. There was no history of any similar illness in the past.

On admission the temperature was 98.8°F., the pulse 90, and the respirations 20. Except for tenderness over the lower abdomen, the general physical examination was negative. The red-cell count was 4,900,000 and the hemoglobin 92 per cent. The white-cell count ranged from 16,300 on October 7 to 22,900 on October 14, with differential counts as follows: on October 7, 26 per cent neutrophils, 67 per cent small lymphocytes and 7 per cent large lymphocytes; on October 14, 23 per cent neutrophils, 52 per cent small lymphocytes and 25 per cent large lymphocytes; on October 21, 22 per cent neutrophils, 60 per cent small lymphocytes and 18 per cent large lymphocytes. Agglutination reactions using typhoid and brucella organisms were negative on October 8 and 9. The heterophile antibody reaction on October 9 was positive in a titer of 1:512. Urinalysis was negative.

The abdominal cramps persisted for 48 hours after admission and subsided with symptomatic treatment. On the 2nd hospital day, the temperature began to rise and the patient developed a low-grade fever that persisted for two weeks, the temperature ranging from 98.8 to 100°F. During that time he lost considerable strength and felt extremely tired. On the 8th day, enlargement of the left posterior cervical nodes was noted, and the swelling persisted throughout the hospital stay. The patient was discharged on the 18th day after having been afebrile for 3 days. The feeling of tiredness persisted for several weeks after discharge.

Diagnosis: infectious mononucleosis.

CASE 4. J. O., a 44-year-old sheet-metal worker, was admitted to a hospital on March 28, 1943, with chief complaints of fever and malaise. He had been fairly well until March 21, when there was onset of malaise and anorexia. He tempted self-medication with proprietary drugs and bed rest, but without relief. He then became aware of chills, sweats and afternoon sweats. Within the next few days began having severe occipital headaches. He consulted

his physician, who found that the temperature was 101°F. There was no cough or other symptoms of upper respiratory infection. The past history was not important except that the patient was employed as a sheet-metal worker in a manufacturing plant. Although he did not handle meat products, he often repaired metal runways used in the processing of meat products.

On admission, the temperature was 101°F., the pulse 110 and the respirations 20. Physical examination was negative. The red-cell count was 4,200,000, the hemoglobin 81 per cent, and the white-cell count 10,400, with 76 per cent neutrophils, 23 per cent lymphocytes and 1 per cent eosinophils. Urinalysis was negative. A blood Hinton test was negative. Agglutination tests on April 2 were reported as follows: typhoid and paratyphoid reactions, negative; undulant-fever reaction, positive in a titer of 1:405. X-ray examination of the chest on April 2 was negative.

The temperature remained elevated for 3 weeks after admission. During the 1st week it averaged 101°F. during the afternoon and evening and was considerably lower in the morning. During the 2nd and 3rd weeks the patient was afebrile in the morning, and the afternoon and evening temperatures varied from 99.6 to 102°F. There was no change in the physical findings. Recovery was uneventful following subsidence of the fever.

Diagnosis: undulant fever.

CASE 5. R. L., a 5-year-old boy, was admitted to a hospital on April 3, 1935, with chief complaints of fever and malaise. He had been well until 8 days prior to admission, when he became listless and fretful. There was general malaise and anorexia. The family physician found that the rectal temperature was elevated, varying between 99 and 103°F. Since there was no improvement after 4 days, hospitalization was advised. The past history revealed the usual childhood diseases. For several months the patient had been drinking raw milk. Adjoining the property on which he lived, there was a large piggery, but no history of contact with pigs could be established.

On admission on January 25, the temperature was 105°F., the pulse 120, and the respirations 36. The patient appeared pale and listless and was quite ill. The significant findings in the physical examination were marked splenomegaly, hepatomegaly and engorgement of the superficial vessels of the abdomen. The red-cell count was 3,640,000 and the hemoglobin 78 per cent. The white-cell count gradually rose from 3400 on January 21 to 5500 on February 27, with differential counts as follows: on January 21, 46 per cent neutrophils, 46 per cent lymphocytes, 6 per cent monocytes and 2 per cent eosinophils; on January 27, 36 per cent neutrophils, 52 per cent lymphocytes, 10 per cent monocytes and 2 per cent basophils; on February 3, 44 per cent neutrophils, 51 per cent lymphocytes and 5 per cent monocytes. Urinalysis was essentially negative. A blood Hinton test was negative. Agglutination tests on January 23 were as follows: typhoid and typhus reactions, negative; undulant-fever reaction, positive in a dilution of 1:32,805 and partially positive in one of 1:98,415. On February 15 and February 20, blood cultures revealed *Br. suis*. On January 21, x-ray examination of the chest was negative.

The temperature remained extremely high during the first 2 weeks of the illness. On January 28, therapy with a brucella vaccine was instituted, and there was a marked rise in temperature following each dose. On February 7, there was some diminution in the size of the liver and spleen, although the patient still appeared quite ill. Late in February, except for the febrile response following the administration of vaccine, the temperature became normal. Later, when the vaccine was discontinued, the temperature remained normal. On March 12, there was a recurrence of fever, and this persisted until March 20. Thereafter, except for an occasional rise to 100°F. during the afternoon and evening, the patient remained afebrile. There was an uneventful recovery.

Diagnosis: undulant fever.

CASE 6. R. H., a 27-year-old veterinarian, consulted his physician in December, 1939, with complaints of weakness and swelling of the scrotum. For several days he had tired easily, and this was followed by a painful swelling of the scrotum. The physician found that the temperature was 102°F. There was no history of urethral discharge preceding the onset of the present illness.

was composed of private patients treated by of us (L. J.); the second comprised patients treated by members of the visiting staff and residents of the Massachusetts Memorial Hospitals; third included patients with contagious disease, ally scarlet fever. A fourth group of cases, in ch healing was effected by draining the post-aural wound, is included for comparison.

In the first group there were 12 cases, all of which were operated on in the manner previously described. The postoperative course was uneventful in all cases; the patients were asymptomatic and temperature remained normal. Complete healing of the postaural wound and drum occurred in an average of twelve days. Two patients had a postaural abscess, and 1 had zygomatic mastoiditis on admission; all these wounds healed by first intention. The shortest hospital stay was six days, a patient leaving with a dry middle ear and a completely healed postaural incision.

An illustrative case is that of a twenty-two-year-old girl who had acute suppurative otitis media two weeks before admission and developed a large swelling over the zygomatic region one week before surgery. Trismus was marked, and a temperature of 101°F. was present. Operation revealed large areas of destruction in the mastoid and a subperiosteal abscess over the zygomatic root. The usual operation was performed except that in addition a stab wound was made over the zygomatic root and this area was drained for twenty-four hours. The sutures were removed in five days. The wound healed by first intention, and the canal was dry in seven days. It may well be that the stab wound was superfluous.

In the second group there were 8 cases of acute mastoiditis, in all of which the wound was closed by primary suture. Since several members of the staff did the operations, several different techniques were used. In general, however, a complete simple mastoidectomy was done. The cavity was irrigated with saline solution and dried, and the mixture of sulfanilamide and sulfadiazine was used to fill the cavity. The wound was closed either in a single layer with black thread or in two separate layers with catgut and silk. In no case was the wound drained. In some cases a myringotomy was done to provide adequate drainage through the middle ear. The average postoperative stay was fourteen days, and the postaural wound was healed and the middle ear was dry in all cases. Two cases required revision, since the wound broke down and the ear continued to drain, and some infected cells were found and removed. The cavity was filled with powder and sewed tightly as before. Healing by first intention and a dry middle ear resulted.

In the third group there were 25 cases. It must be remembered that any surgical procedure attempted on patients with scarlet fever is usually followed by delayed healing, and indeed in some severe cases

of the disease the healing response is an entity scarcely related to that found in patients without scarlet fever. These patients were treated as were the two previous groups, and the operative work was done by several different operators. The sulfanilamide and sulfadiazine powder was used to fill the cavities, and the wound edges closed in one or two layers, depending on the operator. Skin clips were often used for closure. Myringotomy was done when additional drainage facility was in order. No serious complications referable to the mastoid occurred. One patient developed erysipelas around the wound, one had a cervical adenitis requiring drainage, one had a hematoma of the wound requiring aspiration, and another developed a superficial abscess in the line of incision that resolved with hot compresses. The average postoperative stay was twenty-eight days, which is about half as long as the average hospital stay in the pre-sulfonamide days (see below). The postaural wound was healed in an average of nineteen days. It broke down in 9 cases, 6 of which eventually required revision. At the second operation it was usually found that some cells had been overlooked at the first operation. After these were removed the wound was filled with powder and tightly sewed. All these patients made uneventful recoveries. Many of the patients with scarlet fever complicated by mastoiditis were acutely ill, with a high fever. In all cases the temperature returned to normal within one to three days and the patients showed marked clinical improvement.

The fourth group comprised 26 patients with contagious diseases, 24 of them with scarlet fever, who required mastoidectomies in 1939. The average postoperative stay was over fifty-two days, the longest stay being one hundred and eighty-seven days and the shortest ten days. The following complications presented themselves: hemorrhage from the postaural wound; cellulitis of tissues around the wound, extending to the orbit; hemolytic streptococcus meningitis; and a diphtheritic membrane in the postaural wound.

SUMMARY AND CONCLUSIONS

Primary closure of postaural mastoidectomy wounds in 44 cases is reported. This method of treatment has been made possible by the advent of the sulfonamide drugs, which when used locally reach high concentration and virtually sterilize the wound. More than half the cases were those of mastoiditis complicating scarlet fever. In these, it was possible to reduce the period of hospitalization from an average of fifty-two days to twenty-seven days. Patients without scarlet fever went home with dry ears, and the postaural wound healed in an average of fifteen days.

In all of 12 private cases the treatment was successful, the patients being discharged with dry ears and healed postaural wounds. Primary cures were

used in processing meat products. These patients had no direct contact with animals or animal products.

To demonstrate how readily infectious mononucleosis and undulant fever may be confused, a typical case of each disease is presented.

The following cases, each demonstrating an unusual feature of the respective disease, are also discussed: infectious mononucleosis with involvement of the central nervous system, infectious mononucleosis with gastrointestinal manifestations, undulant fever of the malignant variety and undulant fever complicated by epididymitis.

PRIMARY SUTURE OF SIMPLE MASTOID WOUNDS

LEIGHTON F. JOHNSON, M.D.,* AND PHILIP S. SPENCE, JR., M.D.†

BOSTON

THE purpose of this report is to record our experience in 44 cases of acute mastoiditis in which the patients were treated by means of primary closure of the wound after filling the cavity with sulfonamide powder. It will be generally admitted that if such wounds can be closed tightly at the time of operation, the risk of postoperative mixed infections, a prolonged hospital stay and frequent, painful postoperative dressings can be eliminated. With the advent of chemotherapy and its proved efficacy in treating infections, otologists have eagerly sought the best methods of using the sulfonamides in acute surgical mastoiditis.

It seems hardly necessary to state that the two objectives of surgery in acute mastoiditis are to save life and to secure a dry middle ear and thereby restore normal hearing. There obviously can be no compromise with these two fundamental aims in any contemplated change in surgical technic.

The technical demands for primary suture are exacting. The mastoid exenteration must be complete. Great care should be taken to remove all infected cells. The perilyabyrinthian cells are removed until the horizontal semicircular canal is sharply defined. The zygomatic area is thoroughly

cleaned out, and in a number of cases the incision is brought into view. The mastoid cavity is irrigated with normal physiologic salt solution followed by thorough drying of the cavity. If bleeding persists, adrenalin packs may be used to establish complete hemostasis. The cavity is filled with sulfonamide powder. It appears to make little difference in the end result which sulfonamide drug is employed. In the early cases sulfadiazine was used, more recently a combination of sulfadiazine and sulfadiazine powder in the proportion of 3 to 1 has been employed. The local concentration is so great that the mastoid cavity is sterilized and prompt healing ensues. The wound is closed in two layers, with more powder between layers. Interrupted catgut sutures are employed for the subcutaneous tissues, and the Poole suture with black thread is used for the skin.

If the patient's condition remains satisfactory the dressing is not touched for three days. If gauze over the incision is dry, it is not disturbed. On the fifth day, the dressing is again done and stitches are removed. If the middle ear is dry and the postaural wound has healed, the patient may leave the hospital after the seventh day.

The series of 44 patients covered in this report, all of whom were operated on within the last year and a half years, consists of three groups. 1

†Resident in otolaryngology, Massachusetts Memorial Hospitals

ved. Nine lumbar punctures in the 7 days after entry sealed persistently elevated initial pressures. The fluidained yellowish and cloudy and contained 100 to 2000 s per cubic millimeter, of which 88 to 100 per cent were ymophonuclear leukocytes. Pandy reactions continued ngly positive. A hemolytic *Staphylococcus aureus* was own from the spinal fluid as well as from the blood until day before death, when no growth occurred. The sulfazine level did not exceed 7.6 mg. per 100 cc. in the blood 5.5 mg. in the spinal fluid. Despite clinical improvement peratures of 100 to 103°F. continued. On July 25, the tient lapsed into stupor, and then into coma. The respiras and pulse became irregular, and he expired on the lowing day, 24 days after the onset of the illness and 7 ys postoperatively.

Autopsy. The gross anatomic diagnoses were as follows: rombophlebitis of the left and right cavernous sinuses; it superior petrosal sinus and ophthalmic veins; bilateral bital abscesses; basilar purulent leptomeningitis; infarc-

Through the 4-cm. operative defect in the left fronto-temporal region an elevation of brain tissue protruded.

The left frontal and temporal lobes of the brain were noticeably wider than the corresponding lobes on the right. Over both cerebral hemispheres the gyri were flattened and the sulci narrowed. An intense sanguinopurulent exudate covered the entire basilar surface of the brain and was particularly profuse around the chiasm and orbital portion of the frontal lobes, where separation from the dura was exceedingly difficult. There was a cerebellar pressure cone. The lateral, third and fourth ventricles as well as the aqueduct were dilated to about twice their normal size.

Small, irregular, yellowish areas of softness, varying in size from a few millimeters to 2 cm., involved the middle frontal gyrus, precentral gyrus, superior parietal lobule and central white matter of the left hemisphere (Fig. 2). No lesions of this type were found in the right hemisphere.

The cerebral cortex was edematous and in some regions poorly demarcated. The tissue at the lower portion of the

FIGURE 1. *The Sella Turcica, Showing the Distended Cavernous Sinuses and the Softened, Infarcted Pituitary Gland in Situ.*

tion of the pituitary gland; small recent cerebral infarcts. involving the left frontal, parietal and parieto-occipital lobes; cerebellar pressure cone; internal hydrocephalus; and fibrinopurulent pleuritis with empyema (right).

The most significant extracranial finding was encountered in the chest. The right pleural cavity was obliterated in its posteroinferior aspect by thin, easily friable fibrinous adhesions. Separation of the right middle and lower lobes from the chest wall disclosed a thin layer of thick yellowish purulent exudate. The left pleural cavity had a few similar adhesions but neither fluid nor exudate. The portion of the right lung bound to the chest wall showed spotted hemorrhage and exudate. Otherwise the lungs were normal in every respect, and nowhere were they consolidated or infarcted. The larger arteries and veins were patent and free of thrombi.

Both cavernous sinuses were greatly distended by firm, grayish-yellow thrombi, the left more so than the right (Fig. 1). In the left superior petrosal sinus and in both ophthalmic veins similar thrombotic material was found. In both orbits abscesses 1.5 to 2.0 cm. in diameter were encountered in the course of the ophthalmic veins.

left precentral gyrus was softened and hemorrhagic. The large cerebral arteries and veins were patent. No evidence of thrombosis was detected in either of these. The dural sinuses, other than those mentioned, were also free of thrombi.

The cavernous sinuses, sella turcica, pituitary gland and surrounding bone were removed en bloc, fixed in 10 per cent formalin, decalcified and stained with hematoxylin and eosin. The brain was fixed in 10 per cent formalin. Sections were stained with cresyl violet and hematoxylin and eosin. Other organs were fixed in Zenker's fluid and stained with phloxine and methylene blue.

Over the pleura adherent to the thoracic wall on the right there was considerable fibrinopurulent exudate, with some hemorrhage and organization. The subpleural vessels were congested. The underlying lung showed edema and slight hemorrhage into the alveoli. No pneumonitis was present.

In the liver there were scattered foci of lymphocytes not associated with necrosis.

The cells of the granulocytic series in the bone marrow were moderately hyperplastic.

The cavernous sinuses were filled with large, partially organized septic thrombi, consisting of polymorphonuclear

effected in 6 of 8 cases treated by the hospital staff and in 19 of 25 cases of contagious disease.

Primary suture requires close attention to the exenteration of all mastoid cells and to complete hemostasis.

Patients who were studied in the early portion of these cases were kept in the hospital longer than absolutely necessary in order to observe the effects of primary suture. Those admitted later, generally speaking, were allowed to go home in fewer days. Doubtless, results can be improved with standardization of operative technic.

No serious complications were seen in primary closure, even in the cases in which the sinus or dura was exposed. The temperatures promptly returned to normal after every operation, and no intracranial complications were noted.

In some cases the postaural wound ruptured at a short distance, but unless it became necessary to do a complete revision all these wounds healed spontaneously in a shorter time than was required by the earlier method. Sutures were removed about the fifth postoperative day.

CAVERNOUS-SINUS THROMBOPHLEBITIS*

Report of a Case with Multiple Cerebral Infarcts and Necrosis of the Pituitary Body

AVERY D. WEISMAN, M.D.†

BOSTON

ALTHOUGH cavernous-sinus thrombophlebitis is a fairly common clinical entity, its cerebral complications have received surprisingly scant attention. Even such comprehensive volumes as those of Turner and Reynolds¹ and Eagleton² fail to stress intracerebral complications. Courville³ mentions the rarity of brain changes in this disease and holds with most other authors that leptomeningitis is the most frequent secondary pathologic change. Standard monographs and the recent literature confirm the impression that intracerebral complications in cavernous-sinus thrombophlebitis, other than leptomeningitis, are exceedingly rare, and no recorded example of implication of the pituitary gland has been found.

The case reported here offered an opportunity to examine the histopathology of cavernous-sinus thrombophlebitis in detail. The extensive intracerebral complications that were found raised points of practical interest.

CASE REPORT

D. F., a 13-year-old boy, was admitted to the Neurological Service of the Boston City Hospital on July 19, 1942. Seventeen days previously he had acquired a furuncle on his nose. One day after its appearance the left eye became swollen and prominent; within a few hours he became extremely drowsy and entered a local hospital in a comatose state. There he presented a stiff neck and a continuous temperature of 104 to 105°F. The following day he developed a right hemiplegia and proptosis of the right eye. On the 8th hospital day he had a generalized convulsive seizure. Under

treatment with sulfonamides, the clinical state improved slightly, although the spinal fluid showed persistent evidence of meningitis. The patient remained comatose for 11 days. At the end of 2 weeks he was transferred to the Boston City Hospital.

Physical examination on admission revealed an acutely ill patient, with a temperature of 104°F., a pulse of 136, and a blood pressure of 110/70. He was deeply stuporous. He understood simple commands when aroused but was unable to speak. There was moderate proptosis and considerable chemosis bilaterally. The sense of smell and visual acuity could not be examined; a right homonymous hemianopsia was suspected from the response to rough tests at the time of entry, but could not be verified. Both fundi presented edema and hyperemia, with blurring of the nasal margins of the disks. There was no response to painful stimuli on the right side of the face. There was a flaccid right hemiplegia affecting the face, arm and leg. The activity of the tendon reflexes on the right side was increased, with an equivocal Babinski sign on that side. The patient was incontinent.

The red-cell count was 2,500,000, the hemoglobin 45 per cent, and the white-cell count 14,500. The hemoglobin rose gradually to 69 per cent 2 days before death, and a white-cell count of 17,000 to 27,000 was maintained throughout the course of the illness. The nonprotein nitrogen was 28 mg. per 100 cc., the carbon dioxide combining power 36 vol. per cent, and the chloride 95 milliequiv. per liter. The urine gave an alkaline reaction and showed a specific gravity of 1.011, no albumin and no sugar. A rare red cell and an occasional white cell were noted in the sediment.

At the time of entry the initial pressure of the cerebrospinal fluid was 250 mm. The cell count was 2900 leukocytes, of which 1450 were polymorphonuclear leukocytes and 750 were erythrocytes. The fluid was yellowish and cloudy and contained a gelatinous clot. The Pandy reaction was strongly positive, with the total protein 534 mg., the sugar 57 mg., and the chloride 639 mg. per 100 cc.

Shortly after admission a left-sided trephination was performed to rule out subdural abscess, and none was found. The patient was somewhat improved the day after operation and was able to answer questions and to co-operate in a more thorough examination. The presence of a right homonymous hemianopsia was confirmed. Sulfadiazine was administered orally. During succeeding days he was able to move his right thigh, and his speech greatly im-

*From the Department of Neurology, Harvard Medical School, and the Neurological Unit of the Boston City Hospital.

†Assistant in neurology, Harvard Medical School; resident in neurology, Boston City Hospital.

on and stupor—were due to the thrombophlebitis and septicemia. The proptosis, orbital edema, chemosis, facial swelling and papilledema were caused by venous obstruction and lymphedema as well as orbital abscesses and swelling of the brain. The signs of involvement of the ophthalmic

FIGURE 5. Section through One of the Softened Areas Depicted in Figure 2

Note the thrombosed artery between two partially infarcted gyri (cresyl violet).

division of the trigeminal nerve, which was manifested by frontal headache and blunting of sensation over the cornea and forehead, were probably the result of toxic damage and edema.

The unique features of this case that merit special consideration are the multiple foci of necrosis in the left cerebral hemisphere, as a result of which there occurred convulsions, aphasia, homonymous field defect and a right hemiplegia, and the necrosis of the pituitary gland.

Focal cerebral signs in cavernous-sinus thrombophlebitis may arise in several ways. There may be retrograde thrombosis of cerebral veins from a cavernous sinus, with venous infarction or septic cerebral embolism developing from an acute bacterial endocarditis or pulmonary infection, with arterial infarction. A rare complication is a subdural empyema with venous infarction of the cerebrum, as reported by Kubik and Adams,⁵ but their case (Case 6) was associated with a primary sinus infection.

At autopsy the pathogenesis of the foci of cerebral necrosis was not evident. There was no subdural empyema, nor were the cerebral veins thrombosed. The shape and distribution of the lesions and the finding of occluded arteries, on the other hand, left no doubt that these were arterial infarcts. Although the infarcts can be attributed to thrombosed arteries, the source of their occlusion cannot be definitely established. The absence of primary arterial disease and the abrupt onset of the cerebral symptoms suggest embolic occlusion. No endocarditis

or pulmonary-vein thrombosis, however, could be found, which excludes the common origins of such emboli. Another possibility is that the arteries became thrombosed as a result of the contiguous leptomenigitis, but it is difficult to see how this could have occurred without accompanying thrombosis of the thinner-walled veins. The unilaterality of the lesions, limited to the left cerebral hemisphere, led to a careful inspection of the internal carotid artery. Within the cavernous sinus the internal carotid arteries showed a focal arteritis. Polymorphonuclear leukocytes had invaded the coats of these arteries, and over such inflammatory foci there was marked intimal proliferation. These arterial lesions correspond to the experimental infectious angiitis of Winternitz and Le Compte,⁶ who by injecting *Staph. aureus* produced necrosis in the wall of a vein, with thrombosis and an acute arteritis with intimal hyperplasia in an adjacent artery. Although the internal carotid arteries were diseased, there was no evidence of thrombosis. Thus the origin of the emboli remains conjectural.

Necrosis of the pituitary gland due to infarction has not previously been described in cavernous-sinus thrombophlebitis. No symptoms of pituitary insufficiency were exhibited by the patient, but from what is known of pituitary necrosis in other diseases⁷ this would hardly have been expected in so short a time. About 75 per cent of this gland was infarcted. According to Sheehan,⁷ 50 per cent or more of the pituitary gland must be lost before clinical evidence

FIGURE 6 Section through a Thrombosed Artery
Note the periarterial inflammation, and the partial organization of the thrombus (cresyl violet)

of a deficiency appears. With the accurate methods of determining pituitary function that are now available, subclinical deficiencies occurring with destruction of a smaller amount of tissue can be determined. The increasing number of recoveries from cavernous-sinus thrombophlebitis with the use of sulfonamides and penicillin requires recog-

leukocytes, layers of fibrin, fibroblasts and hemosiderin-filled histiocytes (Fig. 3). The sinus walls were necrotic and invaded by polymorphonuclear leukocytes. Both carotid arteries were surrounded by the inflammatory exudate. In a few places polymorphonuclear leukocytes had penetrated the media and intima of the artery. Associated with such

FIGURE 2. Section through the Frontal Lobes, Showing Several Irregular Areas of Softening in the Left Hemisphere.

local arterial infiltrations was a moderate degree of intimal hyperplasia and proliferation of subintimal fibroblasts. No fibrin, however, was deposited on the intima at such points, nor was there any other evidence of partial thrombosis of the artery. In the interstitial tissue between the sinus walls and the carotid arteries the inflammation was of a more chronic character, with an abundance of plasma cells and to a lesser extent histiocytes, some filled with hemosiderin. There was also an increase in fibroblasts.

Although the third, fourth, fifth and sixth cranial nerves were surrounded by suppuration, there was no evidence of

FIGURE 3. Coronal Section through the Cavernous Sinuses. Note the partially organized septic thrombi and the infarction of the pituitary gland. A represents the wall of the cavernous sinus; B, the thrombosed pituitary body; C, the internal carotid artery; D, the third, fourth, fifth and sixth cranial nerves in the wall of the cavernous sinus; and E, the sphenoid bone (hematoxylin and eosin).

direct inflammatory invasion. The myelin sheaths and axis cylinders were intact.

The pituitary gland showed an extensive central necrosis, evidently due to infarction (Fig. 4), and only a thin periphery of intact cells remained. A small number of polymorphonu-

clear leukocytes and red cells were found in the infarct tissue.

No acute osteomyelitis of the adjacent bone was found, nor was there any detectable abnormality of the meningeal membrane of the sphenoid sinus.

The leptomeninges over the cerebral convexities were somewhat thickened but showed no evidence of acute inflammation. Sections of the areas of softening in the cerebrum, previously described, disclosed complete destruction of nerve and glia cells (Fig. 5). Large numbers of histiocytes had infiltrated these areas. There was an increase in the size and number of capillary endothelial cells. Infiltration with polymorphonuclear leukocytes, either within the substance of the brain or around the small vessels, was lacking.

One small artery, cut longitudinally as it passed between two partially infarcted gyri, was completely thrombosed (Fig. 5). Its wall was surrounded but not invaded by lymphocytes and hemosiderin-filled histiocytes. A somewhat larger meningeal artery located near by and cut in cross section was thrombosed, and a fairly fresh collection of necrotic polymorphonuclear leukocytes and red cells filled its lumen (Fig. 6). At one point considerable fibroblastic activity, indicative of organization, was observed. Polymorphonuclear leukocytes and histiocytes both surrounded the artery and infiltrated its adventitia. Thrombosis of these arteries was

FIGURE 4. Section through the Infarcted Pituitary Gland Showing Central Necrosis and an Intact Periphery (hematoxylin and eosin).

unquestionably responsible for the adjacent infarction, but in many similar areas of infarction no thrombosed vessels were found.

Near one of the infarcts many small, discrete and confluent hemorrhages were encountered. These varied from mere local scatterings of red cells to large necrotic zones of hemorrhage. Even though many of the meningeal veins were congested, none appeared to be thrombosed.

DISCUSSION

The partly organized septic thrombi in the cavernous sinuses, the thrombosed ophthalmic veins and the orbital abscesses and edema of orbital tissue are characteristic pathologic changes in cavernous sinus thrombophlebitis and have been discussed in detail by Macewen,¹ Eagleton,² and Turner and Reynolds.³ There was an associated organizing purulent leptomeningitis that by obstruction of the foramen of Luschka was probably responsible for the internal hydrocephalus. The nasal furuncle was doubtless the source of the infection.

The pathological findings provide an explanation for the clinical picture. The general systemic symptoms — that is, malaise, chills and fever, prostra-

junctivas (see colored plate¹¹²), and resembles somewhat the ocular manifestations of argyria. The skin often shows varying degrees of generalized brownish to dull slate color as well as pigmentation of the hyperkeratotic papular lesions.

Mu, Frazier and Pillat,¹⁰⁸ using biopsy material, concluded that the skin and conjunctivas of patients with vitamin A deficiency contain both melanin-building ferments and melanin pigments as shown by the positive Dopa and silver reactions. They also noted that in the skin the melanin-building ferments and melanin pigment are reduced around

Tolmach and Graham¹¹³ report the case of a forty-year-old woman seen in New York who showed skin pigmentation due to vitamin A deficiency. They review the literature and emphasize the rarity of this finding in the white race in this country. Puscaru and Nitzulescu¹¹¹ think that the melanin pigmentation of vitamin A deficiency seen in persons of the darker racial groups should be considered as a manifestation of a special reaction, the intensity of which varies according to the particular capacity of the trophopigmentary tissue of different races, being most reduced in the white race. Pigmentation

†Vagabonds' disease may have an internal as well as an external cause

‡Pigmentation chiefly in cartilage, skin pigmentation less constant

the hyperkeratotic follicle but increased in the near-by hyperplastic epidermis.

Pillat¹¹⁰ suggests that the main purpose of the conjunctival pigmentation is protection from the sun and daylight. Failure of the corneal epithelium to form pigment may be one of the reasons why the cornea sometimes undergoes marked changes (keratomalacia) in severe vitamin A deficiency. Argyria, arsenic ingestion, diminished liver function and the usual systemic disorders producing pigmented skin were all excluded as a cause for the pigmentation.^{109,110} Clinically, other deficiencies were not noticeable. That vitamin A deficiency was the cause of the conjunctival and skin pigmentation was suggested by its frequency in persons with xerosis, keratomalacia and follicular hyperkeratosis (70 to 80 per cent in one series) and its gradual subsidence when these other lesions healed from the administration of cod-liver oil.¹⁰⁹⁻¹¹⁰ Goldsmith¹⁰⁷ emphasizes the possible role of vitamin A deficiency in causing skin pigmentation.

of the skin and conjunctivas due to vitamin A deficiency is probably infrequent in this country because a deficiency severe and prolonged enough to cause xerosis and keratomalacia is but rarely seen.

Pigmentation and Vitamin C Metabolism

There is a considerable literature correlating or at least attempting to correlate skin pigmentation and vitamin C metabolism. Cornbleet¹¹⁴ and others¹¹⁵⁻¹¹⁷ give reviews of this subject. The vitamin C store in the adrenal glands diminishes in guinea pigs placed on a scorbutic diet. Melanin pigment in the skin has been shown to increase when vitamin C depots in the adrenal glands and the rest of the body are depleted and to diminish with administration of vitamin C.¹¹⁴ Pigmentation of the skin is frequent in scurvy and disappears with vitamin C treatment.^{114, 118} Hemosiderin and hematoïdin are formed in scurvy.¹¹⁸ The diffuse pigmentation sometimes seen, however, suggests overproduction of melanin as well as the presence of hemosiderin.¹¹⁸ The hyper-

tion of hypopituitarism as a possible consequence of this disease.

SUMMARY

A case of cavernous-sinus thrombophlebitis with extensive complications is reported. The complications included small cerebral infarctions, purulent leptomeningitis, bilateral orbital abscesses and infarction of the pituitary gland.

The clinical picture and pathology are discussed, with particular reference to the arterial basis of the cerebral infarcts.

Although several thrombosed arteries were found, no source could be ascertained. The possibility of hypopituitarism as a sequel of cavernous-sinus thrombophlebitis is suggested.

MEDICAL PROGRESS

PIGMENTATION OF THE SKIN (Continued)*

HAROLD JEGHERS, M.D.†

BOSTON

MELANOSIS NOT ASSOCIATED WITH AN INCREASED NUMBER OF MELANOBLASTS

THE vast majority of melanin pigmentations encountered in medical practice fit into the group classified by Becker and Obermayer¹⁰² as melanosis not associated with an increased number of melanoblasts (Table 2). Melanin pigmentation results from the activity of melanoblasts normally present in the skin. Many of these follow or accompany drug or inflammatory reactions or various dermatoses and are of special interest to the dermatologist. In evaluating pigmentation one should therefore always inquire concerning a previous skin inflammation or lesions. Lentigo should not be confused with freckles. The former are dark-brown macules, usually 0.5 to 1.0 cm. in diameter, occur on the covered parts of the body as well as the face and hands and appear later in life than do freckles.¹⁰²⁻¹⁰⁴

External factors frequently cause melanin pigmentation. The best-known one is the common coat of tan from exposure to sunlight or to an artificial source of ultraviolet rays. Less frequently roentgen rays, radium rays, alpha rays from thorium-x and heat rays cause a significant degree of pigmentation. Mechanical and chemical irritations

are also important. External irritants play a role in causing the pigmentation of vagabonds' disease. Many agents applied locally, and some taken internally, may photosensitize the skin so that marked pigmentation occurs with only a limited exposure to sunlight.^{105, 106} The disfiguring pigmentation often brings these patients to the dermatologist.

Chloasma

Most pigmentations of interest to the physician result from internal causes. Chloasma is one of these and is defined as a yellowish to brown macular area, larger than common freckles, sharply demarcated and usually localized and increased by, but not dependent on, light.¹⁰⁷ If circumscribed on the face they are usually on the forehead or malar area. The term "liver spots" is sometimes used as synonymous with "chloasma," and because of their frequent association with menstrual and ovarian disorders or pregnancy the term "chloasma uterinum" is often applied to them. They may be associated with a variety of other conditions.^{102, 107} The mechanism of their formation is not clear.

Pigmentation from Vitamin A Deficiency

Adults in China, India and Japan with xerophthalmia and keratomalacia due to vitamin A deficiency have not uncommonly shown a striking pigmentation of the conjunctivas and skin.¹⁰⁸⁻¹¹² In the eye this pigmentation is of a peculiar brownish color, more marked in the lower fornix and bulbar conjunctivas than in the upper lid and bulbar

the corium. No hemosiderin pigment was present in the skin.

It appears, then, that the pigmentation of sprue results from increased activity of the melanoblasts normally present in the skin. The responsible mechanism is not clear. Disease of the adrenal glands appears to be excluded. The chloride excretion in sprue is normal,¹³⁹ as is the histology of the adrenal glands.^{134, 135} Thaysen¹³⁵ has discussed the possible role of deficiency of vitamins B and C in producing pigmentation. Kaufman and Smith¹³⁸ believe that the role of avitaminosis in the production of pigmentary changes requires further investigation. It is of interest to note that pellagra is not uncommonly occurs in sprue patients.¹³⁴

The so-called "butterfly sign," an area of pigmentation of the face, narrow over the bridge of the nose and widening out over the cheeks, is frequently mentioned in the literature. At times it is accompanied by pigmentation of the mouth or tongue. It was for a time considered diagnostic of schistosomiasis, hookworm disease and infection of the urinary tract.¹⁴⁰⁻¹⁴² It was also considered in the earlier literature as a sign of intestinal tuberculosis.¹⁴² Sutton and Sutton¹⁴³ have commented on the supposed relation of mouth pigmentation to ancylostomiasis. It is difficult to evaluate the significance of these signs, but one could readily suspect a nutritional-deficiency mechanism.

Within the last few years 2 patients at the Boston City Hospital, a girl of fifteen and an adult woman, exhibited a curious syndrome of pigmentation of the skin associated with intestinal polyposis.¹⁴⁴ Both had had extensive gastrointestinal resections. Autopsy in each case revealed intestinal polyposis and normal adrenal glands. Pigmentation had been present in the girl before the intestinal operation. The pigment appeared to be melanin and was distributed in an acral fashion about the mouth, on the lips and over the hands and fingers as small dots and round patches. There is said to be a family in Boston several members of which exhibit this syndrome.

It is of interest that Hutchinson¹⁴⁵ in 1896 reported a case of cutaneous pigmentary syndrome in nine-year-old twins and identical with the pictures of our patients. Weber¹⁴⁶ later mentioned that one twin died at the age of twenty from intussusception. This circumstance suggests the possibility of these twins having had polyposis. The syndrome is not unknown in the literature. Metzger, Ohlmann and Half¹⁴⁷ report the case of a nineteen-year-old girl with polyposis and pigmentation of the skin. Polyposis is often familial. The possibility exists that the pigmentation represents an associated pigmentary anomaly rather than the result of a metabolic or nutritional disturbance of intestinal origin.

Pigmentation of the skin may occur in patients with gastrojejunal fistulas. I have seen such a

case, also one of tuberculosis of the ileum with skin pigmentation. Pigmentation of the skin may occur in celiac disease. It is well known that nutritional-deficiency states produce marked changes in the function of the small intestine, including absorptive defects.¹⁴⁸⁻¹⁵⁰

There is an extensive literature indicating that pellagra, which in itself is associated with skin pigmentation and other deficiencies, is frequently secondary to a wide variety of diseases of the stomach, small intestine and colon.¹⁵¹⁻¹⁵³ From clinical experience and perusal of the literature, however, one gains the impression that pigmentation of the skin without pellagrous dermatitis is, if not more frequent, certainly of a much more pronounced degree in diseases of the small intestine than in disorders of the colon.

Color of the Skin in the Anemias

All physicians are familiar with the pallor of the skin seen in patients with anemia. All other factors being equal, the degree of pallor is directly proportional to the loss of hemoglobin. Skin color in anemia patients, however, varies for other reasons than this. Wintrobe¹⁵⁴ gives an excellent account of these.

The lemon-yellow pallor of pernicious anemia can be attributed to the anemia together with mild bilirubinemia. It may also be attributed to the lack of biliverdin in pure hemolytic jaundice. Most patients with pernicious anemia now receive early and continued treatment, so that in contrast with the frequency in the pre-liver treatment era few patients remain untreated long enough to permit this sign of excess pigment metabolism to develop distinctively.¹⁵⁵ Minot¹⁵⁵ states that this characteristic appearance of pernicious anemia patients is about five times as rare as formerly. These patients may develop a brownish type of pigmentation that is either diffuse or blotchy.¹⁵⁶⁻¹⁵⁹ Vitiligo and premature graying of the hair are two other well-known pigmentary disturbances frequently seen.¹⁵⁶ The earlier literature contains many references that report cases of a melanin type of pigmentation of the oral mucosa^{146, 158, 160} (see colored plates^{160, 161}). In the experience of any one hematologist, however, this is a rare finding. The skin pigmentation appears clinically to be of the melanin type. Its pathogenesis is not clear. Formerly the arsenic therapy used was suspected,¹⁵⁹ but this theory is now untenable since patients not on arsenic therapy have shown this type of pigmentation.^{158, 160} The hemosiderin formed in this disorder may be a stimulus. Since absorptive difficulties have been demonstrated in the small bowel¹⁴⁸ the pigmentation mechanism may be similar to that seen in sprue. The role of the avitaminosis is not known. The pigmentation improves with treatment.

Similar pigmentation and vitiligo but probably of a milder degree are sometimes noted in hypo-

pigmentation of Addison's disease may diminish with vitamin C therapy.^{114, 116} It has been suggested that pigment and vitamin C in association with copper occur together in the skin, the pigment apparently serving as the anchor that holds vitamin C.¹¹⁴ Copper apparently hastens the darkening and precipitation of Dopa by ultraviolet rays, whereas vitamin C retards this precipitation.¹¹⁴ Several other writers have suggested that copper may play a role in causing skin pigmentation.^{119, 120} Comment is made on the possibility that disturbance of a copper, vitamin C and melanin balanced mechanism in the skin is the cause of the skin pigmentation in Addison's disease and scurvy.¹¹⁴ Vitamin C, tyrosine and Dopa absorb selectively the erythema-producing ultraviolet rays.¹¹⁴

The failure of some pigmentations to respond to vitamin C therapy has been ascribed to its oral use.^{117, 121, 122} Destruction of ingested vitamin C by infections in the upper bowel and failure of absorption because of achylia gastrica have been given as reasons.¹²² Parenteral administration has been recommended in such cases. Hoff,¹¹⁵ ascribes the skin pigmentation of gastric carcinoma, pernicious anemia, pancreatic disturbances and chronic gastrointestinal disturbances to such a mechanism. Counteraction of pigment formation by the administration of this vitamin is claimed. Chloasma has been reported to respond in a similar manner.^{114, 121, 122} Wilkinson and Ashford¹¹⁷ review the literature dealing with failure of vitamin C therapy in pigmentary disorders. Abt and Farmer¹¹⁶ mention favorable results with the use of vitamin C in treating pigmentation of the skin. The controversial nature of this field is thus apparent.

It has been suggested that photosensitivity on exposure to the sun with subsequent development of pigmentation may in certain cases be related to absence or diminution of certain vitamins, particularly vitamin A or C or both.¹²³

Further evidence of the influence of vitamin C on pigment metabolism is the recent demonstration of the need for this vitamin for the complete metabolism of tyrosine and phenylalanine. Pigmentation of this type appears to be conditioned not only by a vitamin C deficiency but also by the presence or absence of an excess of pigment precursors. Other information relative to vitamin C and pigmentation is discussed in the sections on Addison's disease and ochronosis.

Pigmentation of Pellagra

Pigmentation of the skin usually occurs in pellagra and appears to be of several varieties. The most frequent type is the deep tan or bronze color developing at the site of the pellagrous lesions as the acute phase of the dermatitis subsides.¹²⁴⁻¹²⁶ It is usually seen on the exposed portions¹²⁷—the face, neck and dorsum of the hands and lower legs (see illustrations^{125, 126} and colored plate¹²⁸). It may

develop in areas of the body exposed to irradiation but not to sunlight.^{125, 126} Stomatitis rather than pigmentation is the usual mucous-membrane manifestation.¹²⁴

A roughened, thickened (hyperkeratotic) pigmented area over pressure areas (the elbows, knees and so forth) (see illustrations^{125, 129, 130}) is considered one of the most characteristic skin lesions of pellagra, especially in mild chronic forms or as a sequel between flare-ups of acute pellagrous dermatitis.

Harris and Harris¹²⁵ in their monograph state, "At times there is a brownish pigmentation over the entire body, resembling and with much the same distribution as the characteristic epidermal discoloration seen in Addison's disease." Further simulation of Addison's disease is the occurrence of pellagra of hypotension, subnormal temperature, weakness and various gastrointestinal symptoms.¹²⁵ Many papers discuss the possible relation of the pigmentary syndrome of pellagra to adrenal function.^{125, 131, 132} Occasionally pathologic changes in the adrenal glands have been noted,¹³³ but in many cases with this suggestive clinical association no gross changes were seen in these glands.¹³¹ The occurrence of this type of diffuse pigmentary change in so many systemic diseases suggests strongly that other of the factors discussed in this review may be responsible.

Pigmentation of Sprue and Other Intestinal Disorders

Pigmentation of the skin is of common occurrence in sprue. It was noted by Thaysen in 12 of 34 cases in one series¹³⁴ and 7 of 10 cases in another,¹³⁵ in 22 of 32 patients by Snell^{136, 137} and in 4 of 6 patients by Kaufman and Smith.¹³⁸ The last workers have written an excellent account of all the cutaneous changes, including pigmentation, noted in the sprue syndrome.

The pigmentation is yellowish brown to brown, most characteristically occurring as sharply defined patches or spots, sometimes symmetrically disposed, on the forehead, nose and cheeks, about the lips and jaw and less frequently on the extremities or trunk. The pigmentation may also be diffuse and at times so extensive as to resemble the type seen in Addison's disease. It is exaggerated by exposure to sun, deepens with relapse of the disease and lightens or even disappears during remission or after treatment. The rarity of pigmentation of the mucous membrane of the mouth in sprue has been emphasized.¹³⁴

There has been considerable speculation concerning the nature of the skin pigmentation in sprue. Excessive hemolysis of red cells and jaundice from liver disease are readily excluded as the cause. Kaufman and Smith,¹³⁸ through special stains of biopsy material from a pigmented area, were able to demonstrate conclusively that there was an increase in melanin pigmentation of the basal cell and rete layers of the epidermis with no pigmentation

ed as bronze, tan, brownish yellow, subicteric brownish tan and bister (see colored plates^{183, 184}). pigmentation is not derived from bilirubin, jaundice is extremely rare.¹⁸³ It is further not to be due to the general deposition of siderin pigment or to Gaucher cells in the¹⁸³ Thannhauser¹⁸³ believes it to be due to melanin. Very rarely pigmentation of the mouth¹⁸³; in a reported case biopsy of the mucous membrane revealed the pigment to be melanin.¹⁸⁵ Gaucher cells do not involve the adrenal glands, tuberculous or scar tissue from siderosis of the organ may explain the occasional case with mucous-membrane pigmentation.¹⁸³ The reason for lesser degrees of pigmentation is not clearly understood. A malar flush of the cheeks may occur.¹⁸⁵

Of special diagnostic importance in Gaucher's disease is the wedge-shaped pinguicula-like thickening of the bulbar conjunctivas, brownish to ochre color, their bases abutting against the corneal margin and their apices extending symmetrically toward the inner and outer canthi (see colored plates^{183, 184}). They are readily overlooked unless the eyes are examined in strong daylight.¹⁸³ Thannhauser¹⁸³ states that although he has seen cases of the chronic adult form of Gaucher's disease in which skin pigmentation was present, he has never seen cases in which skin pigmentation was found and the brownish pinguicula-like thickening of the conjunctivas was lacking.

The other type of skin pigmentation has been emphasized by Bloem, Groen and Postma.¹⁸⁵ It occurs as a characteristic symmetrical pigmentation of the lower legs. The lower margin is rather sharply defined just below the level of the ankle, and the upper border is irregular, showing stripe-like projections with normal skin between them and reaching to variable distances below the knee, being most prominent on the anterior aspect of the lower legs¹⁸⁵ (see illustrations^{183, 185}). The color varies from yellowish brown to lead gray.¹⁸⁵ This pigmentation occurs in the absence of varicose veins, even in young adults. Biopsy of the pigmented area from one of the patients of Bloem, Groen and Postma revealed pigment giving a positive reaction for iron, localized in the dermis and some in small vessels and sweat glands, with the melanin content of the skin normal, findings suggestive of hemosiderin pigmentation.

The hemorrhagic diathesis in this disease and possible stasis of the blood in the leg veins from enlarged visceral organs (the liver and spleen) may be one explanation for this hemosiderin type of leg pigmentation. Deposition of the pigment in the corium may account for the lead-brown hue.

Splenectomy done in a patient with Gaucher's disease manifesting hemolytic anemia resulted in the disappearance of generalized pigmentation and the pinguiculas, but not of the pigmentation

of the legs, a point further suggesting that the two types of pigmentation are not the same.^{186, 187}

Skin pigmentation does not occur in the acute infantile form of Gaucher's disease, a point emphasized by Thannhauser¹⁸⁸ as differentiating it from Niemann-Pick's disease. The latter, which occurs only in infants, causes a gray-brown-yellowish diffuse pigmentation of the skin, especially on places exposed to the light (see colored plate¹⁸⁵).¹⁸⁹ The skin pigmentation of Niemann-Pick's disease is believed due to an increase of melanin. Thannhauser¹⁸⁸ believes that since the adrenal glands are infiltrated by Niemann-Pick's cells, the pigmentation syndrome may be similar to that found in Addison's disease.

Pigmentation of the skin is not a prominent feature of Hand-Schüller-Christian's disease or Tay-Sachs's disease.^{190, 191}

Acanthosis Nigricans

Acanthosis nigricans is a curious pigmentary disorder of the skin of considerable general medical interest because of its association with cancer in half the cases reported in the literature. The type not associated with cancer is called benign^{192, 193}; it occurs primarily in children, often appearing at puberty, progressing a variable degree and with an indefinite duration, and usually not causing or being associated with any serious systemic disorder. The skin in both these types has an identical clinical and histologic appearance. Disturbance of hormonal function of the sex glands has been suggested as a cause of the benign form. Other reasons for its occurrence have been given.¹⁹²

Curth,¹⁹³ in a thorough study and review of this subject, lists the extensive evidence correlating the association of acanthosis nigricans with cancer. This type of acanthosis occurs primarily in adults, especially those past middle age. Tabulations given in Curth's paper list its occurrence with various types of cancer as follows: breast, 9; lung, 4; stomach, 50; uterus, 8; liver, 12; pelvis, 4; abdomen, 8; rectum, 2; intestines, 2; ovary, 1, and so forth. These findings afford an excellent rationale for the dictum, "Acanthosis nigricans occurring in an adult is an indication for an exploratory abdominal operation." Curth believes that some property of the associated tumor may activate the skin lesions. Pressure on the intra-abdominal sympathetic nerves fails to explain many of the cases.

The pigmentary syndrome of acanthosis nigricans in its early stages is strikingly similar to that of Addison's disease, including the not infrequent involvement of the mucous membranes of the mouth.

Acanthosis nigricans causes additional skin or mucocutaneous changes, namely, exaggeration of the normal cutaneous markings, hyperkeratosis and verrucous and papillomatous changes (see

chromic microcytic anemia,^{162,163} but never the yellow pallor of pernicious anemia. The reason for the greenish or greenish-yellow color that led a former generation of clinicians to label hypochromic anemia in young girls as chlorosis (green sickness) is not well understood. Modern descriptions of chlorosis do not include the concept of a green pallor. A brownish hue of the skin in chlorosis is said to be much rarer than in the idiopathic hypochromic microcytic anemia of middle-aged women.¹⁶⁴

Pigmentation of the skin was frequently noted by Bomford and Rhoads^{165,166} in patients with refractory anemias. It varied from light to deep brown, was either spotty or diffuse and tended to be especially prominent on the exposed surfaces. In some cases a grayish or slate color was noted. Hemochromatosis was occasionally seen as a complication.^{165,167} These phenomena were especially noted in refractory anemia of the type with partly mature cellular marrow. Hemosiderin is thus to be strongly suspected as the cause of the pigmentation. It may stimulate melanin production directly in the skin or, more likely through deposition in the adrenal glands.

The studies of Whipple and Bradford¹⁶⁸ indicate that pigment abnormalities simulating hemochromatosis are of common occurrence in Mediterranean disease (erythroblastic type of anemia). Iron-staining pigment was noted in many organs but not in the skin. The adrenal glands were smaller than normal, with abundant iron-staining pigment in the glomerular zone. Grossly the skin looked pigmented. This pigmentation is difficult to evaluate since the disorder occurs in racial groups — Italians, Greeks, Syrians and Armenians — whose skin is normally of a dark complexion.

Ordinarily one associates the yellow color of jaundice with the hemolytic anemias, an association true in most cases. Not to be overlooked is the presence of hemoglobinemia and methemalbuminemia in certain of them. Fairley's^{169,170} classification of hemolytic anemias — hemoglobinuria, methemalbuminemia and hyperbilirubinemia; methemalbuminemia and hyperbilirubinemia; and hyperbilirubinemia alone — indicates the complexity of the problem of pigments in this group. The influence of these on skin color is not clear.

Pigmentation of the lower legs about and above the ankles probably of the local hemosiderin variety, appears to be not uncommon in congenital hemolytic jaundice^{171,172} (see illustrations^{171,172}) and sickle-cell anemia (see illustrations^{173,174}). Ulcers of the legs are frequent in these disorders. The pigmentation may occur about them or the healed scars, and occasionally without ulcer formation.

Pigmentation in the Lymphoma Group

Pigmentation of the skin aside from the discoloration caused by local skin lesions is one of the various dermatologic manifestations noted in

diseases of the lymphoma group.¹⁷⁵⁻¹⁸⁰ Jaundice may also be present with the lymphoma. Epstein and MacEachern¹⁷⁷ in a thorough study of 438 patients with diseases in this group, noted pigmentation of the skin in 15 (10 per cent) of 151 patients with Hodgkin's disease, in 2 of 122 with lymphosarcoma, in 2 of 90 with myeloid leukemia, in 1 of 60 with lymphatic leukemia and in none of 10 with acute leukemia or monocytic leukemia. Cole¹⁷⁹ noted diffuse pigmentation of the skin in 4 of 13 patients with Hodgkin's disease. Aside from the green color of local lesions, a diffuse olive tint of the skin may occur with chloroma.¹⁸⁰ A striking degree of melanin-type pigmentation in a patient presenting the clinical picture of a lymphoma would therefore be suggestive but not diagnostic, of Hodgkin's disease.

The skin pigmentation is brownish or bronze, often diffuse, with accentuation in the skin folds and may closely resemble that seen in Addison's disease. At times it is in the form of chloasma patches. The responsible factor is undoubtedly melanin. At times the skin manifestations resemble those of acanthosis nigricans.¹⁸¹ The hair may change color and become lighter.¹⁸⁰ Pigmentation of the mucous membranes of the mouth appears to be extremely rare in Hodgkin's disease.^{179,181,182} There are many reasons why pigmentation of the skin is frequent in Hodgkin's disease; arsenic therapy, generalized pruritus with scratching, x-ray treatment, irritation of the abdominal sympathetic nerves or pressure on the adrenal veins caused by enlarged nodes, malnutrition and avitaminosis are among the possible causes.^{178-180,182} Erythroderma due to a lymphoma may be accompanied or followed by skin pigmentation.¹⁸⁰ Direct involvement of the adrenal glands by a lesion of Hodgkin's disease is among the rare causes of Addison's disease.

Within recent years at Boston City Hospital there have been carefully studied 2 biopsy-diagnosed cases of Hodgkin's disease each with a degree of diffuse skin pigmentation resembling that seen in severe Addison's disease. There was no mouth pigmentation in either case. Skin biopsy showed only melanin pigmentation. Electrolyte studies of the blood sodium and chloride were normal. Erythroderma, local skin lesions, scratching, arsenic or x-ray therapy and involvement of the adrenal glands were excluded as causes of the pigmentation in these cases. Both patients were poorly nourished.

Pigmentation in Gaucher's Disease and Niemann-Pick's Disease

Pigmentation is frequent in adults with Gaucher's disease, and at least two distinct types have been described. One of these is localized in the exposed parts — the face, neck and hands. It may be diffuse or occur as chloasma patches vari-ously de-

tation. It has been my experience that medical students and interns have a hazy conception of this disorder. Textbooks on dermatology discuss it under pediculosis corporis. In a large municipal hospital one not infrequently encounters patients whose skin pigmentation is best explained on this basis. There is a considerable earlier and particularly foreign literature on the subject. The Germans refer to the disease as *Vagabondenkrankheit*.²¹⁸ Other synonyms are "vagabondism" and "vagabonds' discoloration." It has been defined as "a disease simulating morbus addisonii, particularly found in tramps and vagrants." From the literature^{102, 107, 218-223} and our own experience, the typical patient is a man in the older age group, unkempt in his personal habits, usually with pediculosis corporis and a history of infrequency of bathing or even changing the clothes and dietary deficiency, with or without alcoholism. Lesser degrees may occur in neglected elderly and female persons. The face—unless the patient is much outdoors—and the extremities show less pigmentation than does the body. The pigmentation is light to dark brown, and is accentuated about the waist and groins, between the thighs, in the axillas and over the back of the neck and upper back (see illustration²²⁴). The skin may show evidence of bites of pediculi and many linear scratch marks. Of interest is the frequent reference to pigmentation in the mouth,^{218, 219, 223} even in patients dying from other causes, with demonstration of normal adrenal glands at autopsy. Biopsy of the mucous membrane has been reported to show melanin,²²⁰ and this has been our experience in several such patients in whom normal electrodermal studies excluded Addison's disease. Bathing, local treatment of the skin lesions, clean clothes, good diet and multiple-vitamin therapy often cause the pigmentation to diminish in intensity. It is worth remembering that such cases may closely simulate the pigmentary features of the Addisonian syndrome. The skin pigment is melanin, with the melanoblasts in the basal epidermal layer Dopa-positive and the chromatophores in the corium Dopa-negative.²²⁰

Becker and Obermayer¹⁰² classify vagabonds' disease with the melanosis due to physical factors. Undoubtedly the lack of bathing, irritation from pediculi, scratching, unclean clothes, perspiration, toxic substances produced by pediculi and so forth are important. Nutritional deficiency is undoubtedly additive and may accent the melanin-producing ability of the above factors. Goldsmith¹⁰⁷ considers vitamin A deficiency important in vagabonds' disease, especially if the conjunctivas show melanosis. Deficiencies of vitamin C and the vitamins of the B complex may be equally significant, but relative data are not available. Of interest is György's²²⁵ observation that pediculosis is common in rats with chronic riboflavin deficiency but

is not observed in those deficient in other factors of the vitamin B₂ complex, and that riboflavin by mouth has a curative effect on this type of pediculosis in rats. Whether this concept holds for human beings is unknown. There appears to be no good explanation for the oral pigmentation noted in such patients.

Ochronosis

Patients with alkaptonuria cannot completely catabolize the tyrosine and phenylalanine of their food and tissue protein, so that an intermediate product, homogentisic acid, remains. Urine containing homogentisic acid is of normal color when voided but on standing turns brown or black.²²⁶ Fishberg's test²²⁷ enables alkaptonuria to be diagnosed immediately from a single drop of urine. Alkaptonuria is commonly considered an inborn error of metabolism present at birth. Over a period of years a pigment substance is deposited in cartilage,¹² the eye and to a lesser degree in the skin, causing, in later years of life, noticeable pigmentation and arthritis of the spine and large joints. Cardiac disturbances may also occur. Pomeranz, Friedman and Tunick²²⁸ have recently emphasized the roentgenologic features of this arthritis. The curious finding of calcification of the intervertebral cartilages and osteoporosis of the vertebral bodies enables the diagnosis of ochronosis to be made roentgenologically.

Exogenous ochronosis due to absorption of phenol used to dress wounds and ulcers, formerly frequent, has probably disappeared since the introduction of modern antiseptics.

Smith²²⁶ believes that Pick's explanation of the mode of production of the pigment in this disease is most plausible namely, "that, through the action of the oxidative ferment tyrosinase, the phenol substances in the exogenous group and the homogentisic acid molecule in the endogenous group are changed into melanin pigment, which is deposited in tissues." Virchow,²²⁹ in 1866, in studying histologic sections of darkly pigmented cartilage, noted that the pigment granules microscopically appeared pale yellow or ochre, hence the name "ochronosis" applied to deposition of pigment in the body tissue of patients with alkaptonuria.

Pigmentation of cartilage causes the ears and occasionally the nose or knuckles to appear blue, the predominant hue being, no doubt, the optical effect of pigment deep below the epidermis layer of the skin (see colored plates²³⁰⁻²³¹). The skin may become pigmented, especially as a butterfly-shaped brown pigmentation over the nose and cheeks or even more diffusely (see illustration²³⁵).^{230, 231, 236} Because the pigment granules are prominent in the deeper corium the skin pigmentation is apt to be a dark brown blue. Skin pigmentation is never so prominent a feature as is pigmentation of cartilage. At times the hands are pigmented.²³⁰

apy, with reappearance of the pigmentation crises due to rehydration.²⁵⁴ A melanin-pressing activity based on work with animals ascribed to the cortical hormone by Hamilton.²⁵⁵ There is a growing belief that the pigmentary changes are related in some way to vitamin C metabolism, as previously pointed out. Sodeman,²⁴⁹ Hoff,¹¹⁵ Wilkinson and Ashford¹¹⁷ and others give convincing but in part theoretical reasons for the validity of this belief. In vitro experiments show that vitamin C influences the Dopa reactions.^{114, 256} Several workers have reported that pigmentation in Addison's disease has improved with vitamin C therapy.^{116, 257, 258} Curiously enough, this idea appears to have attracted little attention. Rothman²⁵⁶ has recently produced convincing evidence that vitamin C metabolism influences skin pigmentation in Addison's disease. His work suggests that vitamin C may act to diminish hyperpigmentation due to a reducing action on preformed melanin rather than to prevent its formation. Rothman²⁵⁶ used serial colored photographs, silver and Dopa-stained skin biopsy material and the threshold of an erythema dose of ultraviolet light to study the influence of treatment on the pigmentation of Addison's disease. He confirmed the general impression that adequate control with cortical hormone and salt is without noticeable effect on skin pigmentation. He was then able to demonstrate, in the case of a thirty-seven-year-old woman, who was kept in good condition by continuous salt therapy, that the administration of 500 mg. of vitamin C daily by mouth for six months bleached the skin to such a degree that it could be readily recognized in colored photographs. Discontinuance of the vitamin resulted in steady darkening. The serum ascorbic level had been normal before the experiment was started.

Pigmentation in Pheochromocytoma

The malignant form of pheochromocytoma of the adrenal medulla commonly produces an entirely different clinical picture from the one characterized by attacks of paroxysmal hypertension, pallor, cold and clammy extremities, palpitation, headaches and other symptoms usually noted with the benign-tumor form of pheochromocytoma. Pigmentation is not listed as one of the features of the benign form.²⁵⁹ Weight loss, cachexia and skin pigmentation of the malignant form may produce a syndrome closely resembling Addison's disease.²⁶⁰

Pigmentation in Acromegaly

Although the influence of the hormone of the pars intermedia of the pituitary gland, and possibly a separate melanophore hormone affecting skin pigmentation, has been established for lower forms of animal life, this influence in human beings has not been established. Of interest is the recent

report by Fournier et al.²⁶¹ of successful treatment of vitiligo with a pituitary melanophore preparation both for local treatment of vitiliginous areas and for parenteral injection in regions remote from such areas.

Cushing,²⁶² in commenting on the pituitary control of dermal pigments, stated that pituitary disorders are likewise accompanied by appreciable pigmentary disturbances, although less conspicuously so than is Addison's disease. "The complexion of an acromegalic," he wrote, "as is well known, noticeably darkens in color, whereas the reverse is true of hypopituitary states in which the skin shows, in addition to its other distinctive peculiarities a characteristic pallor." Pigmentation of the skin in acromegaly is strikingly evident in many of the published photographs of such patients.^{263, 264} It is yellowish to brown and due to melanin; it occurs either as small frecklelike spots (see illustration²⁶⁴) or more diffusely, is prominent on the exposed surfaces but at times is noticeable on other parts of the body, and is said to be more frequent in women than in men. There are but few comments concerning involvement of the mucous membranes. Davidoff²⁶³ in a careful study of the clinical picture of acromegaly noted cutaneous pigmentation in 46 of 100 cases. Atkinson²⁶⁵ in reporting a more elaborate study of over 1600 cases remarks on the frequency of pigmentation but does not give the actual incidence. The mechanism of the pigmentation is not clear. Excess activity of a pigment-producing or pigment-controlling hormone of the pituitary gland is an explanation that, although attractive, requires further study for its final understanding and acceptance.

Pigmentation in Cushing's Syndrome

The term "Cushing's syndrome" is applied to a striking clinical picture²⁶⁶⁻²⁶⁸ noted in association with cancer or adenoma of the adrenal cortex, basophil pituitary adenoma, probably with adrenal hyperplasia and adrenal hyperplasia alone, all such patients almost invariably showing in the pituitary gland the cellular changes noted by Crooke.²⁶⁸ The face is often flushed and reddish purple (see illustration²⁶⁶). Large purplish striae of the lower abdomen and upper thighs are frequent (see illustration²⁶⁶). Albright²⁶⁸ has emphasized the thin, reddish, possibly transparent skin. Extreme susceptibility to bruising and ecchymosis is frequent. All these color changes in the skin are easy to discern.

Cushing,^{266, 267} in his description of this syndrome mentioned pigmentation of the skin as a minor and not constant feature; he noted it in only 5 of 12 cases. Haymaker and Anderson²⁶⁹ in an extensive review of the literature of this disorder likewise assign pigmentation to the less consistently recorded features. Unfortunately, most papers give but little information about pigmentation other

Failure of the ears to show transillumination of light, due to pigment in cartilage, is diagnostic of ochronosis (see colored plate²³⁰). The cerumen of the ears and axillas may be pigmented.

Smith,^{226, 230} in 1942, published a detailed and stimulating account of the eye changes in ochronosis that probably occur in almost every case. He reports 4 cases and mentions others not reported, and stresses that ochronosis is far more frequent than is generally believed. The eye changes include pigmentation of the scleras, diagnostically distinct localized brown areas on the bulbar conjunctivas and pigment spots in the corneal limbus — best seen with slit-lamp observation. One of Smith's papers²³⁰ contains seven colored pictures of these eye changes. Patients with alkaptonuria should have a careful ophthalmologic study, including slit-lamp observation, for detection of early evidence of ochronosis.

Considerable interest has centered in the recent reports of alkaptonuria experimentally produced in guinea pigs by placing them on a diet deficient in vitamin C and feeding them 0.5 gm. of *l*-tyrosine daily.²³⁷ The addition of 5 mg. of ascorbic acid caused the homogentisic acid in the urine to disappear within one or two days and to reappear within one to three days after withdrawal of the ascorbic acid. Similar experimental results were obtained with two normal human subjects. Alkaptonuria has also been experimentally produced in rats from phenylalanine feeding.²³⁸ This work clearly indicates that the metabolic handling of tyrosine and phenylalanine is dependent on the presence in the body of an adequate amount of vitamin C. Using this information, Sealock, Galdson and Steele²³⁹ treated a sixty-five-year-old man suffering from alkaptonuria and ochronosis with large doses of vitamin C. Even doses of 4 gm. daily had no effect on the output of homogentisic acid. With large daily doses of vitamin C, however, the urine failed to turn dark even after standing several days. These writers suggest that their results do not preclude the possibility of a continued high intake of the vitamin in early life preventing the deposition of melanotic pigment in later years. This therapeutic suggestion would be well worth a trial if a patient with early ochronosis were encountered in clinical practice. The role of vitamin C in pigmentation appears a bit clearer from this work.

Pigmentation of Addison's Disease

Pigmentation of the skin is universally recognized as a constant and characteristic feature of Addison's disease. Its absence in chronic proved cases has been considered exceptional enough to merit a case report in the literature,^{240, 241} although it is generally agreed that in the rapidly developing type of disease pigmentation is occasionally of minimal degree or absent.

The pigmentary syndrome of Addison's disease has been more thoroughly and adequately studied than that of any other systemic disorder with cutaneous pigmentation.²⁴²⁻²⁴⁶ Chemical evidence²⁴⁷ and histologic evidence¹⁹⁵ show the pigment to be melanin. Other than increased melanin pigmentation, histologic sections are not characteristic. Pigmentation is most marked in regions normally pigmented or exposed to light or pressure. It appears particularly on the face, the neck, the back of the hands and particularly the knuckles (see illustrations^{248, 249, 250} and colored plates^{246, 248}). Pigmentation of the mucous membranes of the mouth and occasionally of the conjunctivas and vagina is an almost constant feature. Pigmentation of creases in the palms and soles and of the axillas and groins often develops. Pigmentation is diffuse, but pressure points and body folds may cause accentuation. The pigment color varies from grayish to brown. Minute black, frecklelike pigment may occur. The areolae, nipples and genitalia are often strikingly discolored. Vitiligo is not too rare (see illustration²⁴⁵).

Some papers discuss the possible mechanism of the pigmentation, whereas others simply state that it is not known. Sodeman²⁴⁹ in a recent review gives an excellent account of the literature.

The usual and older, but not proved, explanation states that it results from disease of the medulla rather than that of the cortex.²⁴² The mechanism suggested is that the diseased medulla, being unable to retain its normal store of epinephrine, releases it into the circulation, from which it or its oxidation product or precursor is deposited in the epidermal layer, eventually to form melanin. The similarity of epinephrine in chemical structure to its precursors tyrosine and dihydroxyphenylalanine has already been commented on. According to this hypothesis, Addison's disease in the acute form — chiefly cortical involvement — has but little pigmentation, whereas the chronic form, with both the medulla and the cortex destroyed, shows marked pigmentation. Against this theory are the pigment cases with an apparently good medulla but an atrophied cortex. Adrenalectomy in experimental animals does not usually cause pigmentation.²⁴² A recent report suggests that adrenalectomy may influence pigment metabolism if the vitamin C metabolism is changed at the same time.²⁵⁰ The influence of sulfur metabolism has been another cause discussed.²⁵¹

Most recent authorities state that control of the patient with modern hormone and salt therapy usually has no consistent or striking influence on the skin pigmentation.^{252, 253} Harrop et al. studied their cases with serial colored photographs of skin pigmentation. In fact, the occasional bleaching effect noted has been attributed to mechanical wearing away of the skin²⁵² and the edema of the skin likely to develop with the

apy, with reappearance of the pigmentation crises due to rehydration.²⁵⁴ A melanin-producing activity based on work with animals ascribed to the cortical hormone by Hamilton.²⁵⁵ There is a growing belief that the pigmentary changes are related in some way to vitamin C metabolism, as previously pointed out. Sodeman,²⁴⁹ ff,¹¹⁵ Wilkinson and Ashford¹¹⁷ and others give convincing but in part theoretical reasons for the validity of this belief. In vitro experiments show that vitamin C influences the Dopa reactions.^{114, 256} Several workers have reported that pigmentation in Addison's disease has improved with vitamin C therapy.^{116, 257, 258} Curiously enough, this idea appears to have attracted little attention. Rothman²⁵⁶ has recently produced convincing evidence that vitamin C metabolism influences skin pigmentation in Addison's disease. His work suggests that vitamin C may act to diminish hyperpigmentation due to a reducing action on preformed melanin rather than to prevent its formation. Rothman²⁵⁶ used serial colored photographs, silver and Dopa-stained skin biopsy material and the threshold of an erythema dose of ultraviolet light to study the influence of treatment on the pigmentation of Addison's disease. He confirmed the general impression that adequate control with cortical hormone and salt is without noticeable effect on skin pigmentation. He was then able to demonstrate, in the case of a thirty-seven-year-old woman, who was kept in good condition by continuous salt therapy, that the administration of 500 mg. of vitamin C daily by mouth for six months bleached the skin to such a degree that it could be readily recognized in colored photographs. Discontinuance of the vitamin resulted in steady darkening. The serum ascorbic level had been normal before the experiment was started.

Pigmentation in Pheochromocytoma

The malignant form of pheochromocytoma of the adrenal medulla commonly produces an entirely different clinical picture from the one characterized by attacks of paroxysmal hypertension, pallor, cold and clammy extremities, palpitation, headaches and other symptoms usually noted with the benign-tumor form of pheochromocytoma. Pigmentation is not listed as one of the features of the benign form.²⁵⁹ Weight loss, cachexia and skin pigmentation of the malignant form may produce a syndrome closely resembling Addison's disease.²⁶⁰

Pigmentation in Acromegaly

Although the influence of the hormone of the pars intermedia of the pituitary gland, and possibly a separate melanophore hormone affecting skin pigmentation, has been established for lower forms of animal life, this influence in human beings has not been established. Of interest is the recent

report by Fournier et al.²⁶¹ of successful treatment of vitiligo with a pituitary melanophore preparation both for local treatment of vitiliginous areas and for parenteral injection in regions remote from such areas.

Cushing,²⁶² in commenting on the pituitary control of dermal pigments, stated that pituitary disorders are likewise accompanied by appreciable pigmentary disturbances, although less conspicuously so than is Addison's disease. "The complexion of an acromegalic," he wrote, "as is well known, noticeably darkens in color, whereas the reverse is true of hypopituitary states in which the skin shows, in addition to its other distinctive peculiarities a characteristic pallor." Pigmentation of the skin in acromegaly is strikingly evident in many of the published photographs of such patients.^{263, 264} It is yellowish to brown and due to melanin; it occurs either as small frecklelike spots (see illustration²⁶⁴) or more diffusely, is prominent on the exposed surfaces but at times is noticeable on other parts of the body, and is said to be more frequent in women than in men. There are but few comments concerning involvement of the mucous membranes. Davidoff²⁶³ in a careful study of the clinical picture of acromegaly noted cutaneous pigmentation in 46 of 100 cases. Atkinson²⁶⁵ in reporting a more elaborate study of over 1600 cases remarks on the frequency of pigmentation but does not give the actual incidence. The mechanism of the pigmentation is not clear. Excess activity of a pigment-producing or pigment-controlling hormone of the pituitary gland is an explanation that, although attractive, requires further study for its final understanding and acceptance.

Pigmentation in Cushing's Syndrome

The term "Cushing's syndrome" is applied to a striking clinical picture²⁶⁶⁻²⁶⁸ noted in association with cancer or adenoma of the adrenal cortex, basophil pituitary adenoma, probably with adrenal hyperplasia and adrenal hyperplasia alone, all such patients almost invariably showing in the pituitary gland the cellular changes noted by Croke.²⁶⁸ The face is often flushed and reddish purple (see illustration²⁶⁶). Large purplish striae of the lower abdomen and upper thighs are frequent (see illustration²⁶⁶). Albright²⁶⁸ has emphasized the thin, reddish, possibly transparent skin. Extreme susceptibility to bruising and ecchymosis is frequent. All these color changes in the skin are easy to discern.

Cushing,^{266, 267} in his description of this syndrome mentioned pigmentation of the skin as a minor and not constant feature; he noted it in only 5 of 12 cases. Haymaker and Anderson²⁶⁹ in an extensive review of the literature of this disorder likewise assign pigmentation to the less consistently recorded features. Unfortunately, most papers give but little information about pigmentation other

than that it occurs. Frequent mention is, however, made to it in the many published case histories.

Pigmentation of the skin in Cushing's syndrome appears to be of two types, both of which may occur in the same patient. One is a melanin type, as evidenced by a darker skin in the upper part or exposed parts of the body or accentuation of pigmentation over pressure areas, in the body folds, axillas and groins, under the breasts and so forth. This type is neither frequently nor prominently discussed. Bruising is common in this disorder, which, along with the elevated red-cell count, may predispose to hemosiderosis of tissues with pigmentation. Whether such a mechanism or stimulation of melanin formation by a hormonal mechanism occurs is not clear. If Cushing's syndrome is dependent on hyperadrenocorticism, it would be paradoxical to ascribe its pigmentation to this type of adrenal dysfunction when the classic example of marked pigmentation, Addison's disease, is produced by a destructive adrenal lesion. It remains to be clearly stated whether a marked melanin pigmentation is directly related to the Cushing syndrome.

In contrast to this is the much more evident hemosiderin type of brownish to bronze pigmentation frequently noted over the lower legs, from the ankle to below the knee. It is strikingly evident in many of the published photographs of patients (see illustrations^{266, 267, 269}) and is specifically considered by Weber²⁷⁰ to be hemosiderin in type. The tendency for patients with the Cushing's syndrome to bruise easily and bleed into tissue, the thinness and fragility of the skin, the poor muscle tone of the lower leg muscles, which limits muscular activity as an aid to the return of venous blood from the legs, the pendulous abdomen and the elevated red-cell count all predispose to frequent gross or microscopic deposition of blood in the skin of the lower legs, with transformation to hemosiderin pigmentation, and probably to some stimulation of melanin formation.

Pigmentation in Simmonds's Disease

In contrast to the frequently observed pigmented skin of acromegaly and the plethoric and dark skin of Cushing's syndrome is the pale and sometimes yellow skin noted so frequently in Simmonds's disease, a disorder attributable to a destructive process of the anterior lobe of the pituitary gland. The adrenal glands in Simmonds's disease are usually less than normal in weight and show marked cortical atrophy but relatively little medullary change, a finding that led Sheehan²⁷¹ to remark, "In view of the condition of the suprarenals it is of interest that skin pigmentation of Addison's disease type is practically never seen." Escamilla and Lissner,²⁷² in a review of 101 pathologically proved cases in the literature, noted that skin pigmentation was seen in 24 per cent of them.

Williams²⁷³ and other endocrinologists stress the lack of skin pigmentation in patients with Simmonds's disease who manifest an Addison type of syndrome is one of the most reliable signs in differentiating it from true Addison's disease. They also emphasize that, even when skin pigmentation is present, it is of minimal degree and not likely to be confused with the classic pigmentation of Addison's disease. This was strikingly true in 3 cases seen by me.

Sheehan²⁷¹ emphasizes pallor of the skin in this disease, attributing it in part to indoor existence. He further comments on a possible endocrine origin contrasting the pallor of Simmonds's disease with the purplish plethoric facies of Cushing's syndrome. The yellow tint of the skin in Simmonds's disease, especially the type resembling myxedema, may well be due to the low metabolic rate. The existence of carotenemia was demonstrated in at least one case of this disease.⁵⁸

Hamilton²⁵⁵ noted that cortical hormone (desoxycorticosterone acetate) suppressed melanin formation by melanophores of explants of skin ectoderm from embryos of a species of fowl (New Hampshire Reds). He remarks, "This result may be of interest in view of the fact that clinically it is observed that Addison's disease is accompanied by a darkening of the skin as though the normal inhibitor of pigment formation had been removed with destruction of the adrenal cortex."

It is of interest that pigmentation of the skin is but rarely seen with anorexia nervosa, a disorder likely to be confused with some forms of Simmonds's disease. Offhand, one might expect to see pigmentation due to avitaminosis in this condition but curiously enough, signs of vitamin deficiency in anorexia nervosa are uncommon. In complete starvation specific vitamin deficiencies have not been noted, probably because the reduced energy requirements are satisfied by the utilization of body tissues that are in themselves complete foods.²⁷⁴ No doubt the low level of the metabolism in anorexia also diminishes the requirements for vitamins.^{274, 275}

Elaboration by the pituitary gland of a substance stimulating melanin production in the skin and inhibition of melanin production by the corticoid hormone, as just commented on, constitute a balanced control readily upset by disease in either organ.

Pigmentation in Other Pituitary Syndromes

Pallor of the skin is of common occurrence in hypopituitarism.²⁶² Cushing emphasized that persistent freckles on exposed areas of an otherwise pale skin are characteristic of most hypopituitary cases (see illustrations of facies of patient with chromophobe adenoma²⁶⁷). In Fröhlich's syndrome the skin feels soft and delicate and is sometimes peculiarly white, thin and transparent—the skin

and "alabaster skin".²⁷⁶ The face frequently presents a bright malar flush to form the so-called "roses-and-cream" variety of complexion. Pigmentary spots, walnut-stain colored, small and rounded, resembling freckles and ranging in size from pinhead to pea size, are not uncommon²⁷⁶ (see illustration²⁷⁶). Similar spots may be seen in the cutaneous dystrophias of the Laurence-Moon-Biedl type (see illustration²⁷⁶). Diffuse pigmentation is evidently extremely unusual but has been commented on as occurring in an atypical variant of the Laurence-Moon-Biedl syndrome.²⁷⁷ A similar frecklelike pigmentary syndrome is noted in pituitary dwarfism.²⁷⁸

Pigmentation in Hyperthyroidism

A survey of a dozen or more standard general medical works, as well as of monographs on thyroid disease, lead one to conclude that pigmentation of the skin is noted in 3 to 70 per cent of patients with hyperthyroidism. The pigmentation may be diffuse or chloasma in type, may be limited to exposed surfaces of the body or be widespread, and varies in intensity from being barely noticeable to being as dense as that seen in Addison's disease.^{279, 280} Hyperthyroidism of long standing is more likely to have the marked and diffuse type. The pigmentation is brownish and is due to melanin. Rarely it is present in the mucous membranes of the mouth. The marked accentuation of pigmentation of the eyelids occasionally noted in hyperthyroidism is called "Jellnick's sign."¹⁰⁰ The pigmentation often fades following adequate therapy.

Equally striking in some patients is the marked degree of vitiligo. In fact, the literature contains not infrequent references to the association of hyperthyroidism, vitiligo and alopecia areata.²⁸¹

The mechanism of the pigmentation is not clear. The similarity of the pigment precursor tyrosine, the thyroid hormone thyroxine (a phenyl ether of the amino acid tyrosine with four iodine atoms) and di-iodotyrosine is to be commented on. Melanogenesis is inhibited through the sympathetic pathways. Sympathetic stimulation is predominant in hyperthyroidism, so that this mechanism, if operative at all, can explain vitiligo but not the pigmentation. Diversion of tyrosine for thyroid use might explain vitiligo, but again not the more consistently present pigmentation. The complex inter-relation of the pituitary and adrenal glands in hyperthyroidism is well known. The influence of these two structures on pigmentations has already been discussed. The possibility of deficiency of vitamins, especially those of the vitamin B complex, because of the known influence of increased metabolism on its utilization,²⁸² may in some way be concerned with pigmentation in this disorder. The rarity of pigmentation of the melanin type in myxedema has been mentioned.

Pigmentation and the Gonads

"One of the outstanding characteristics of a human male castrate is the paleness of the skin," according to Edwards et al.¹² These writers, using the Hardy recording spectrophotometer, studied skin color in castrates and eunuchoid patients before and after treatment with androgenic hormones. Untreated castrates were shown to have more carotene, slightly less melanin but more melanoid and generally diminished hemoglobin pigment in their skin than did normal males. It is of interest that this combination of pigmentary findings is somewhat similar to the normal pattern for women.¹¹ Eunuchoids with secondary hypogonadism showed no carotene change from normal and a variable modification of other pigments. One eunuchoid showed findings similar to those of the castrate group.¹² Treatment of the castrates with androgens increased both the melanin and the melanoid, reduced the carotene and returned the hemoglobin quantity and distribution pattern to normal. It was concluded that androgens have a profound influence on the vascularity and pigmentation of the entire human skin.

Hamilton and Hubert.²⁸³ using castrate and eunuchoid men, showed that tanning of the human skin after exposure to ultraviolet rays is abetted by the presence and negated by the absence of effective levels of male hormone substance in the body tissues and fluids. Hamilton²⁸⁴ noted disappearance with androgen therapy and reappearance on its discontinuance of the pigmented color of the skin below the eyes noted in a castrate male adult. He likened the changes in color about the eye with those noticeable in some women during various parts of the menstrual cycle. With the use of explants of skin ectoderm from embryos of New Hampshire Red fowl, it has been shown that testosterone is far more potent in its action on melanophores than are any of the female hormones and expands both the red and the black ones.²⁸⁵

Hamblen and Cuyler¹⁴ reported that the average daily androgenic titers in the urine of true blonds were distinctly lower than those of marked brunets. Hamilton²⁸⁵ concludes that "both the tanning process and its dependence on hormones for photograph-like 'development' are somewhat similar in women to those described in men, capable of induction in women by male hormone substance and influenced by female as well as by male hormones." Many other examples of in vitro or in vivo experiments demonstrating the influence of sex hormones on pigment metabolism and pigmentation are on record.^{286, 287} Variations in skin pigmentation during the menstrual cycle are well known.^{107, 288, 289} It has been suggested that the influence of estrin on melanogenesis is concerned chiefly with the normal distribution of pigment. Rocca²⁹⁰ has reported success with the topical application of an ointment containing estradiol in a climacteric pa-

tient with chloasmalike areas of skin pigmentation. The explanation suggested was that "estrin causes the disappearance of the abnormal pigmentation through a local effect on the melanocytes when it is applied on the skin or when it acts on the pituitary gland if used in injections, thus inhibiting the melanophoric hormone." The skin of women with arrhenoblastoma, the masculinizing tumor of the ovary, is said to become darker.²⁹¹

Although the details are not completely established, it is apparent that both the amount and the ratio of the male and female sex hormones influence the degree and normal sexual differences of distribution of melanin pigmentation of the skin in human beings. Control of pigmentation by gonadal hormones must therefore be considered along with the influence of the pituitary and adrenal glands in evaluating pigmentary disturbances in endocrine disorders.

Pigmentation in Pregnancy

Pigmentation of the skin is practically universal during pregnancy.²⁹²⁻²⁹⁴ It usually starts about the face, where it is known as chloasma gravidarum and varies considerably in intensity. It appears oftener as brownish areas of chloasma than as a diffuse pigmentation. Brunets manifest it more than do blonds. It is greatly intensified by sunlight. Besides the face, increase in pigmentation is noticeable in the linea alba, on the breasts, in and about the nipples and about the vulvar and anal regions.²⁹³ Nishizaki²⁹⁴⁻²⁹⁷ studied skin pigmentation in pregnant women, using a tintometer to grade color changes. Studying Japanese women, he demonstrated that the pigmentation increased over the entire skin as well as in certain characteristic areas where it was especially noticeable. He correlated the degree of pigmentation with various factors constituting the process of labor and requisite for the normal completion of labor, and concluded that the degree of pigmentation indicates to some extent whether a woman is well adapted to the process of pregnancy. As is well known, the hyperpigmentation clears considerably after pregnancy, but varying degrees of permanent residua in certain areas — the nipples and areolas, the linea nigra and so forth — may remain and constitute presumptive clinical evidence of a past pregnancy.

A hormonal control of the pigmentation of pregnancy is generally acknowledged, but the mechanism has not been clearly shown. It is of interest that injections of estrin are said to intensify pigmentation in certain areas, that is, the areolas.²⁹⁰

Occasionally, development of pregnancy in women suffering from a disorder characterized by skin pigmentation accents the degree of pigmentation.^{298, 299} This is especially true of the pigmentation of neurofibromatosis.²⁹⁹

Pigmentation in Parathyroid Syndromes

Ectodermal disorders are present in chronic hypoparathyroidism. Although dryness, roughness, puffiness, thickening and scaling of the skin are often observed, it appears that pigmentation is rare but possible.³⁰⁰ Skin pigmentation does occur with hyperparathyroidism.

Miscellaneous Diseases with Melanosis

Many other diseases not adequately described in the literature may be associated with melanin pigmentation of the skin. Still's disease, rheumatoid arthritis, certain of the tropical diseases such as Kala-azar and schistosomiasis, senile chronic peritonitis, cachexia due to tuberculosis and malignancy, and cirrhosis of the liver are other examples. The association of skin pigmentation with polycystic disease of the kidneys has been repeatedly mentioned in the literature.^{301, 302} Ljapman and Friedberg³⁰³ discuss the influence of subacute bacterial endocarditis in causing skin pigmentation. It is not seen in the active stage of this disease, but may occur to a striking degree in the bacteria-free stage. They also comment on the café au lait pallor so characteristically seen in this disease. Pottenger³⁰⁴ describes a bronzing of the skin that he believes indicates a disturbance in fat metabolism. This color differs from sun tan. It clears with treatment utilizing the heat-labile factor found in lecithin-rich foods. Whether this disturbance is related to melanin metabolism is not known.

(To be concluded)

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE COUNCIL

Annual Meeting, May 22, 1944

THE annual meeting of the Council of the Massachusetts Medical Society was called to order at 7:00 p. m. in the Georgian Room of the Hotel Statler, Boston, on Monday, May 22, 1944, by the president, Dr. Roger I. Lee, Suffolk; 218 councilors were present (Appendix No. 1).

The Secretary presented the record of the stated meeting held February 2, 1944, as published in the *New England Journal of Medicine*, issue of March 9, 1944.

Dr. David Cheever, Suffolk, moved the approval of this record. This motion was seconded by Dr. Charles A. Worthen, Essex South, and it was so ordered by vote of the Council.

REPORTS OF COMMITTEES

Executive Committee—Dr. Michael A. Tighe, Middlesex North, secretary.

This report, which is as follows, was presented by the secretary:

The Executive Committee of the Council met on April 12, 1944. It reviewed the report of the Committee on Membership. It approved this report and the recommendation contained therein. The report will be presented to the Council later in this meeting.

The Executive Committee reviewed the report of the Committee on Cancer. It approved this report and the recommendation contained therein. The report will be offered later in this meeting.

The Executive Committee reviewed the report of the Committee on Public Relations and approved it. The report will be offered later in the meeting.

The Executive Committee reviewed the report of the Committee on Postwar Loan Fund and recommends that this matter be laid on the table until the Council meeting in February, 1945, so as to afford time for its discussion by the district societies and opportunity for the members of the Society as a whole to express themselves on it through a return postal-card survey. Action on this recommendation will be sought later in this meeting when the committee's report is formally before the Council.

Dr. Tighe moved the acceptance of the report. This motion was seconded by Dr. William M. Collins, Middlesex North, and it was so ordered by vote of the Council.

Committee on Publications—Dr. Richard M. Smith, Suffolk, chairman.

The chairman announced that the committee had no formal report to offer. He spoke of a joint conference that this committee had held with the Committee on Legislation in compliance with a directive of the Council given at its last meeting. He added that the Committee on Legislation would report on this conference later in the meeting.

Dr. Smith also said that the *Journal* had received a 25 per cent increase in its allotment of paper. He spoke of how helpful this was in meeting what had

become a pressing problem. This increase, he added, was in recognition of the fact that many copies go to the armed forces.

Dr. Lee said that this report was accepted as a report of progress.

Committee on Arrangements—Dr. Gordon M. Morrison, Middlesex South, chairman.

This report, which was offered by Dr. Morrison, is as follows:

The results of the committee's work cannot be properly appraised and reported on until after this current meeting is over. We can, however, report that during the past year we have held a number of meetings at which the program and other arrangements for this annual meeting have been worked out. The program that will be presented tomorrow and Wednesday covers a wide range of topics that we hope will be of interest to the general practitioner. We have tried to include timely subjects and to secure speakers who are widely known in their respective fields.

We wish to call attention at this time to the exhibits, both scientific and commercial, and to request that everyone pay a visit to them. About 40 per cent more booths have been sold this year than ever before, and all members should register at each booth some time during the meeting. It should be remembered that it is the money received from these exhibits that enables us to pay the expenses of more guest speakers and for larger meetings each year, and unless all members show an interest in the exhibits, we shall not continue to attract them.

From the financial point of view this meeting is sure to be successful. The income has already been greater than ever before, and we hope to turn over to the Society profits of at least \$4000.

In this connection, it is interesting to review the loss or gain of former committees on arrangements (Table 1).

TABLE 1. *Loss or Gain from Annual Meetings.*

YEAR	LOSS OR PROFIT	AMOUNT
1929	Loss	\$1099.36
1930	Loss	2209.29
1931	Loss	3189.20
1932	Loss	1250.66
1933	Loss	332.43
1934	Loss	898.57
1935	Loss	1784.03
1936	Loss	1157.45
Total loss		\$11,920.97
1937	Profit	119.33
1938	Loss	578.26
1939	Loss	84.35
1940	Profit	708.79
1941	Profit	1065.05
1942	Profit	3287.75
1943	Profit	1750.16
1944	Profit	4000.00
Total gain	(estimated)	\$10,268.47

From 1929 through 1936, the committees were a drain on the finances of the Society—one year the cost of the meeting was nearly \$3200—and for those eight years the total cost amounted to nearly \$12,000. For the eight years since 1937, there have been only two years when there was no profit, and for those years a total profit of \$10,268.47 has been turned over to the treasurer of the Society. This striking change in the financial results of these meetings corresponds with the date that our executive secretary, Mr. Boyd, took over their business management, and we believe that great credit is due him for what

he has accomplished. Moreover, we sincerely trust that next winter the Committee on Finance will recall these figures and see that he is properly recompensed.

To all of those who have aided this committee this year we offer our thanks.

Dr. Lee announced that this report was accepted as a report of progress.

Committee on Ethics and Discipline — Dr. Ralph R. Stratton, Middlesex East, chairman.

The report, which was offered by the chairman, is as follows:

During the past year the usual list of complaints of unethical action on the part of fellows, requests for advice concerning ethical procedure and so forth have been received. Most of these complaints were of minor importance and easily settled in committee.

Three complaints of unethical practice were of so serious a nature that they should be mentioned briefly.

First, a fellow was accused of vicious and deliberate violation of Section 4 of Article IV, Chapter III, of the *Principles of Medical Ethics of the American Medical Association*. Section 4 reads as follows:

When a physician does succeed another physician in the charge of a case, he should not make comments on or insinuations regarding the practice of the one who preceded him. Such comments or insinuations tend to lower the esteem of the patient for the medical profession and so react against the critic. Investigation satisfied the committee concerning his guilt, and his resignation from the Massachusetts Medical Society was requested and received. The episode was considered closed.

Second, a fellow was accused of violation of Section 3 of Chapter II, of the *Principles of Medical Ethics of the American Medical Association*. Section 3 reads as follows:

A physician is free to choose whom he will serve. He should, however, always respond to any request for his assistance in an emergency or whenever temperate public opinion expects the service. Once having undertaken a case, a physician should not abandon or neglect the patient because the disease is deemed incurable; nor should he withdraw from the case for any reason until a sufficient notice of a desire to be released has been given the patient or his friends to make it possible for them to secure another medical attendant.

This accusation was of a rather serious nature. Investigation and hearings showed the accusation to be justified. After a formal discussion, the fellow, although a member of the Society for a number of years, was judged to be totally ignorant of what constitutes ethical practice. He was verbally castigated by the members of the committee and was referred to the President for a severe admonition. This admonition was administered and so reported to the committee. The case was placed on file.

Third, three fellows were accused of deliberate violation of Section 7 of Article I, Chapter III, of the *Principles of Medical Ethics of the American Medical Association*. Section 7 reads as follows:

Physicians should expose without fear or favor, before the proper medical or legal tribunals, corrupt or dishonest conduct of members of the profession. All questions affecting the professional reputation or standing of a member or members of the medical profession should be considered only before proper medical tribunals in executive sessions or by special or duly appointed committees on ethical relations. Every physician should aid in safeguarding the profession against the admission to its ranks of those who are unfit or unqualified because deficient either in moral character or education.

This accusation was thoroughly investigated. A hearing was given to each of the accused. As a result, the committee unanimously judged each of them guilty of said violation and requested their resignations from the Society. Subsequently the resignation of each of the

fellows was received and referred to the Committee Membership for recommendation to the Executive Committee of the Council. When the Executive Committee shall have passed on these resignations, the incident shall be considered closed.

Dr. Stratton moved the acceptance of the report. This motion was seconded by Dr. William A. Chapin, Hampden, and it was so ordered by vote of the Council.

Committee on Medical Education — Dr. Robert Monroe, Norfolk, chairman.

No report.

Committee on Membership — Dr. Harlan F. Newton, Suffolk, chairman.

This report (Appendix No. 2) was offered by Dr. Newton, who suggested that, inasmuch as it had been received in advance of the meeting by the Councilors it not be read. It was the will of the Council that this report should not be read.

Dr. Newton referred to the *Journal of the American Medical Association* and particularly to the data on medical licensure in the United States and territories appearing in the issue of May 13, 1943. He summarized an editorial that appears in the same issue as follows:

Throughout the years, failures among foreign graduates were very high. Nearly 50 per cent of foreign graduates examined failed in 1943, these examinations being conducted in the United States, Hawaii, Alaska and Puerto Rico, as compared with a failure of only 1 per cent of graduates of approved medical schools.

Dr. Newton moved the acceptance of the report. This motion was seconded by Dr. John B. H. Norfolk, and it was so ordered by vote of the Council.

Dr. Newton then said that the Committee Membership, in this report, recommended that Chapter V, Section 2 (b) of the by-laws of the Massachusetts Medical Society remain unchanged.

He moved the adoption of this recommendation. This motion was seconded by Dr. Cheever, and it was so ordered by vote of the Council.

Committee on Public Health — Dr. Francis P. Denison, Norfolk, chairman.

No response.

Committee on Medical Defense — Dr. Arthur Allen, Suffolk, chairman.

The report which was offered by Dr. Allen, is as follows:

We now have ten malpractice suits pending; of these three new cases have developed during the past year. It has not been possible to dispose of any case during the year.

The total bills for legal services for 1943 was \$439. The committee has no other expense.

Our attorneys are handling our affairs with satisfaction. Although our budget for the coming year has been reduced from \$2000 to \$1500, we believe that there is much likelihood that the total amount will be used.

Two members of the committee are in active military service, and the work is being carried on by the three remaining members.

Dr. Allen moved the acceptance of this report. His motion was seconded by Dr. Albert A. Hornor, Norfolk, and it was so ordered by vote of the Council.

Committee on Society Headquarters — Dr. William H. Robey, Suffolk, chairman.

This report, which is as follows, was offered by Dr. Robey:

The committee has held a few meetings since its last report, and some important improvements have been made in the rooms of the Massachusetts Medical Society. These changes have been made possible by the generosity of the trustees of the Boston Medical Library. They have consisted of a complete renovation of the space formerly occupied by the *Journal of Bone and Joint Surgery* and also of the room now occupied by the assistant to the Secretary. The latest change is the installation of a closet for the storage of certain journals and memoranda belonging to the Society. Considerable time was spent on this project, and the closet has been finally installed at the cost of \$180, which is a considerable reduction in the price of the space originally planned. It is also hoped that in time we shall install an office of information, renovate the lobby of the Library and place a suitable sign on the façade of the Library indicating the headquarters of the Society, but these last improvements will have to wait until materials are available.

Dr. Robey moved the acceptance of this report. This motion was seconded by Dr. Daniel B. Reardon, Norfolk South, and it was so ordered by vote of the Council.

Committee on Finance — Dr. Francis C. Hall, Suffolk, chairman.

No report.

Committee on Industrial Health — Dr. Dwight O'Hara, Middlesex South, chairman.

This report (Appendix No. 3) was offered by Dr. O'Hara. He said that this committee had continued to work in close co-operation with certain state agencies, the Associated Industries of Massachusetts, the New England Conference of Industrial Physicians, the American College of Surgeons, the Procurement and Assignment Service and the Council on Industrial Health of the American Medical Association. He added that two of the members of the committee had attended the annual meeting of the last organization, held in Chicago on February 14, 15 and 16, 1944.

He spoke of a register that the committee continued to maintain of those physicians who might be interested in practicing industrial medicine. He added that the supply of physicians was in excess of the demand.

He called attention to the committee's report of October 7, 1942, which stated that the committee was "most perplexed to know how to reach . . . those who are employed . . . in the small plants that are now rushing war production." He added that it was obviously impossible for the small plants to establish a real medical department, although three quarters of the workers are employed in such establishments. He said that a promising approach

toward solving this problem in Massachusetts had been made by certain community-health nursing associations which had offered special part-time service to the small plants in their respective areas.

He stated that a third industrial-health program, to be held in Springfield, had been prepared but that it had to be canceled because a suitable meeting place could not be secured and because of lack of evidence of local interest and support.

Dr. O'Hara said that, during the winter, the committee's attention was called to federal legislation calling for appropriations to state departments of labor to promote industrial health. He said that the committee had disapproved this legislation, having the support of the chairman of the Committee on Legislation of the Society.

He added that the present period of unprecedented industrial activity and the dependency of industry on the good health of the workers for a high production rate made the time ripe for establishing the principles of industrial medicine in plants where they had never been thought of before.

Dr. O'Hara moved the acceptance of the report. This motion was seconded by Dr. Cheever, and it was so ordered by vote of the Council amid applause.

Massachusetts Committee on Procurement and Assignment — Dr. Reginald Fitz, Suffolk, chairman.

This report (Appendix No. 4) was offered by Dr. Fitz.

Dr. Fitz moved the acceptance of this report. This motion was seconded by Dr. George L. Schadt, Hampden, and it was so ordered by vote of the Council.

Dr. Fitz moved that the President be authorized to establish a Postwar Planning Committee of such size and composition as he deemed advisable. This motion was seconded by Dr. Carl Bearse, Norfolk, and it was so ordered by vote of the Council.

Dr. Fitz moved that the Committee on Procurement and Assignment be discharged. This motion was seconded by Dr. Charles F. Wilinsky, Suffolk.

The Secretary, when addressed by the President in connection with this motion, said that inasmuch as the Massachusetts Committee on Procurement and Assignment was not a committee of the Society but a part of the War Manpower Commission, a federal agency, it was not subject to discharge by the Council.

Dr. Lee said that he took great pleasure in reversing a previous opinion expressed by him on this subject and ruled that this committee might be discharged, so far as the Society was concerned. It was so ordered by vote of the Council. (Dr. Fitz was applauded as he left the platform.)

Committee on Legislation — Dr. Brainard F. Conley, Middlesex South, chairman.

The report, which is as follows, was presented by the chairman:

The Wagner-Murray-Dingell Bills remain the same as stated in our last report. This committee believes, however, that each member of the Society should be on the alert at all times for reappearance of activity on the part of those interested in promoting compulsory health insurance.

Members of the committee have spoken before approximately seventy medical, social and service organizations throughout the Commonwealth, educating the members of those organizations concerning just how the Wagner-Murray-Dingell Bills tend to endanger the American way of living.

Perhaps the most generous and valuable piece of work done in the matter of acquainting the general public with this proposed national legislation was that done by the alumni of Tufts College Medical School at their annual dinner in March. Invaluable services were rendered at that time through the instrumentality of a member of this committee, namely, Dr. William E. Browne, who arranged for Dr. Morris Fishbein, editor of the *Journal of the American Medical Association*, to address the meeting and also had the address broadcast over a radio hookup. This committee expresses its grateful appreciation both to the alumni of Tufts College Medical School and to Dr. Browne.

On February 2, 1944, the following motion was passed by the Council:

That the Committee on Legislation meet with the Committee on Publications to the end that methods of education in medical economics be contrived.

On April 29, the chairmen of these committees met and discussed this motion and decided to have a meeting of both committees on the afternoon preceding this meeting of the Council. Both committees met at 3:30 this afternoon, and a round-table discussion was conducted. It was decided to limit the discussion to medicine in New England.

It was stated and understood that the Committee on Publications, through Dr. Nye, had already invited contributions from all district secretaries and all chairmen of standing and special committees. It was voted that for six months the Committee on Legislation and the Committee on Public Relations should be urged to contribute such matter as is pertinent for publication in the *New England Journal of Medicine*. This should cover the Blue Cross, the Blue Shield, cancer clinics, federal aid, loans for home-coming medical officers and similar subjects.

Dr. Conley moved the acceptance of the report. This motion was seconded by Dr. John B. Hall, Norfolk, and it was so ordered by vote of the Council, amid applause.

Committee on Public Relations—Dr. Albert A. Hornor, Suffolk, secretary.

The report, which was offered by Dr. Hornor, is as follows:

(1) There was a progress report from the Committee Appointed to Look into the Possibility of Better Publicity for the Massachusetts Medical Society. After considerable discussion by the Committee on Public Relations it was finally moved by Dr. Pelletier and duly passed that the former committee be encouraged to seek knowledge of needs for better publicity and ways of obtaining better publicity.

(2) The major part of the evening was devoted to a discussion of the Emergency Maternal and Infant-Care Program, as administered by the Division of Child Hygiene of the Massachusetts Department of Public Health under the direction of the Children's Bureau of the United States Government.

President Lee had invited Dr. Getting, commissioner of health of the Commonwealth of Massachusetts, to meet with the Committee on Public Relations and discuss this question. Dr. Getting arrived at 8:00 o'clock and was most helpful in answering every question which was presented to him by members of the Committee on Public Relations. It was evident that Dr. Getting seeks the help of the Massachusetts Medical Society in the administration and modification of the program as needed to afford the best possible care for

the families of soldiers and at the same time have it the way that the members of the Massachusetts Medical Society think best.

(3) Dr. Fallon's report about the meeting between the organizations and representatives of the Massachusetts Medical Society, held under the auspices of the Farm Bureau Administration in Worcester City Hall on February 9, 1944, was read. There was good accord between the farm organizations and the medical profession as represented at that meeting. What the farmers want is group hospital and medical care coverage by the Massachusetts Medical Society, as a result of the meeting and previous conversations between the farmers and the Blue Cross and Blue Shield, it seems very likely that it will be obtained in the near future.

(4) A report of the Subcommittee on Tax-Supported Medical Care to the Committee on Public Relations was made as follows:

(a) The Technical Advisory Committee of the Department of Public Welfare met with Dr. Mandelstam, adviser to the department. It was agreed, subject to the approval of the Massachusetts Commissioner of Public Welfare, that physicians and surgeons should be compensated for services rendered in understaffed hospitals, persons eligible for state-supported medical care. It was also agreed, subject to the approval of the Massachusetts Commissioner of Public Welfare, that fees should be 25 per cent below the Blue Shield schedule, and on medical cases \$4 should be paid for the first visit in the hospital and \$2 for subsequent visits.

(b) At the last meeting of the Committee on Public Relations the matter of dissatisfaction with the *State Formulary* was referred to the subcommittee. The Council had previously adopted a resolution approving the *Formulary* in principle and urging physicians treating state supported cases to accept minor inconveniences as a public service in the interest of proper economy. The subcommittee has inquired into the workings of the *Formulary* and believes that the original action of the Council should be supported, that the inconveniences to the profession, the druggists and the patients have not been greater than could reasonably have been expected, and that the department has been entirely reasonable and flexible in making adjustments regarding complaints. The *Formulary* now being revised so as to include corrections based on experience.

This report was accepted by the Committee on Public Relations.

Dr. Pelletier reported that in Franklin County the district society had decided to charge full rates for attendance tax-supported patients. This action was approved by members of the Committee on Public Relations with a formal vote.

Dr. Hornor, in presenting the report, called the Council's attention to the fact that it was fully set forth in the sheets of advance information. He asked permission to submit it by title only. In this the Council acquiesced.

He moved that the report be received. This motion was seconded by Dr. Donald Munro, Suffolk, and it was so ordered by vote of the Council. Dr. Hornor said the report contained no recommendations.

Dr. Richard Dutton, Middlesex East, was recognized by the chair. He spoke as follows in connection with Item 4 (b) of the report, which concerns the *State Formulary*:

Because of expressed dissatisfactions, the Committee on Public Relations reviewed the recent vote of the Council regarding the resolution approving the so-called "*State Formulary*." This committee reaffirmed its previous position. The *Formulary* has been approved by the Committee on Public Relations, by the Executive Committee and by the Council itself. The Committee on Public

lations now asks reapproval of its position. With such overwhelming endorsement, it seems almost hopeless to urge further consideration by the Council but, to some at least, it seems as if such approval would carry with it the voluntary surrender of one of the most cherished rights of the medical profession.

The minor or major inconveniences of the *Formulary* to the medical profession, to the druggists and to the patients, mentioned by the committee, are only trivial matters. Whether or not the department has been reasonable and flexible, as they claim, is immaterial, and revisions and corrections of the *Formulary* will not affect the fundamental issue involved.

This issue is whether or not the Council deliberately tends to approve in principle the right of the State Department of Public Welfare, or any other department, to even the right of the Massachusetts Medical Society itself, to dictate to the individual physician what he shall prescribe and in what quantities.

Because a few physicians and druggists may have been scrupulous is no reason for the Society to endorse totalitarian tactics. There are plenty of proper channels through which to check these abuses.

If we are to continue to have old-age assistance, let's keep it a self-respecting insurance, for which we are all contributing; and let's remember that such patients are just as much entitled to the newer drugs advertised in the *New England Journal of Medicine* and elsewhere as are their next-door neighbors, perhaps in slightly better circumstances. Such statements as, "Reimbursement by the State Department will be limited to these items" and "Prices listed are maximal," which occur in the *Formulary*, are foreign to American medicine and to American independence.

But above all, let's not give away the right of the physician to prescribe for his patient according to his own best judgment.

I hope the Council will not approve the *Formulary* in principle.

Dr. Dutton moved that Item 4 (b), so far as it relates to the *Formulary*, be not approved by the Council. This motion was seconded by Dr. Brainard Conley, Middlesex South.

Dr. Bagnall said that he had a very profound respect and admiration for Dr. Dutton, but that he disagreed with him in his interpretation of the portent of this section. He pointed out that, at a previous meeting, the Council had approved the *Formulary* in principle. He added that Dr. Dutton's dissatisfaction had been brought into the Committee on Public Relations and that the matter was referred to the Subcommittee on Tax-Supported Medical Care. He said that this subcommittee, of which he was chairman, decided to stand by its original recommendation and to ask the Council to reaffirm its endorsement of the idea. He added that it had the approval of the Committee on Public Relations and of the Executive Committee.

Dr. Bagnall denied that there was in this item any invasion of the right of the physician to prescribe what he wanted to prescribe. He called attention to the fact that many hospitals indulge in the practice of having a *formulary* and that this does not mean that, under all conditions, the physicians practicing in those hospitals are obligated to follow it. He added that, by the same token, whenever the doctor wanted to prescribe a drug not contained in the *Formulary* and the use of the drug was reasonable and proper, the State Department of Public Welfare would interpose no objection.

Dr. Bagnall said that there was nothing fixed in the matter of the *Formulary* and that revisions will be made from time to time, depending on changes in price or demands by physicians. He added that this was emphasized in the October 27, 1943, issue of the *Bulletin of the Massachusetts Pharmaceutical Association*, and he quoted from this bulletin as follows:

The Department of Public Welfare has agreed that druggists should not be confined to these items mentioned in the *Formulary*, but may dispense all items called for by prescriptions issued by doctors. It is the purpose of the Department of Public Welfare to urge all doctors to conform, so far as may be possible, to those items in the *Formulary*. This formulary will be amended with prices changed to meet market conditions.

Dr. Bagnall said that the Massachusetts Department of Public Welfare had approved this bulletin before it went to press. Dr. Bagnall quoted from a letter received by him, as chairman of the committee, from the Department of Public Welfare, as follows:

On January 3d I gave you in essence the contents of a letter which is in the process of being drawn up, indicating to local boards that the department will reimburse for the initial purchase of goods not on the *Formulary*, or priced in excess of the *Formulary*, and that we intend to supply the local boards with enough information so that repetition of excess price or purchase of goods not on the *Formulary* will not occur. In the exceptional instances we expect the doctors will give adequate reason for the necessity of exceptions, and they will be made.

Dr. Conley asked for an annunciation of the principle involved. Dr. Bagnall said that we were being called on to approve the idea that the Department of Public Welfare was doing the proper thing in issuing a *formulary* for the guidance of those doctors who were practicing under its control or influence.

Dr. Conley said that to his mind the question involved here was whether or not the Council should approve of the Department of Public Welfare telling the doctor what he should or should not write for. He expressed the opinion that the Council should not so approve.

Dr. Bagnall, in denying that any such question was involved, said that the Department of Public Welfare had "not restricted the right of any physician to prescribe anything which you and I would think was all right for him to prescribe, regardless of whether or not it is on the *Formulary*." Dr. Schadt asked Dr. Bagnall why, under such circumstances, there was a need for a *formulary*. Dr. Bagnall reiterated the thought that the *Formulary* was a guide.

Dr. William A. R. Chapin, Hampden, said that the Department of Public Welfare can, and probably will, do this thing regardless of the action of the Council. He added that he was going to vote for the motion because he was a member of the Massachusetts Medical Society and was not particularly interested in the saving of money by the State Department of Public Welfare at the cost of the doctor's privilege and right to recommend to a patient

the use of any drug which he, the doctor, thought necessary and that he did not believe that it should be necessary for the doctor to seek the permission of the Department of Public Welfare before so doing.

The motion was lost on a vote by the Council.

Committee to Meet With the Medical Advisory Committee of the Industrial Accident Board — Dr. Daniel J. Ellison, Middlesex North, chairman.

This report (Appendix No. 5) was offered by Dr. Ellison.

He made many explanatory additions to the report. He emphasized the fact that henceforth the surgeon on duty in hospitals will be paid for all emergency work done by him on industrial accident cases and that an emergency as used in this connection does not necessarily end with the first treatment but may extend over many days. He spoke of the acceptance by the chairman of the Industrial Accident Board of the theory that the costs of the medical care of those injured in industry should be assessed to industry and not to the medical profession.

He spoke of circumstances under which injured workmen who are policyholders in the Blue Cross may acquire better accommodations than those allowed by the Industrial Accident Board. Such a policyholder of a semiprivate-room contract with the Blue Cross may, on his own election, occupy such semiprivate quarters and the Blue Cross will pay the difference between the sum allowed by the Industrial Accident Board and that charged by the hospital for this type of accommodation, when such a difference exists.

If the attending doctor, however, decides that the exigencies of a particular case require hospital accommodations of a type that cost more than that allowed ordinarily by the Industrial Accident Board, the Blue Cross will not piece out the difference in such costs. The Industrial Accident Board will consider every such case individually and decide in each whether or not the additional costs are warranted.

Dr. Ellison said that freedom of choice of physician is provided for by the law and that, in cases in which the patient knows no doctor, that principle may be maintained by supplying him with a list of the members of both the regular and courtesy staffs of the hospital in which he finds himself and another list selected by the insurance company from among the members of the regular hospital staff.

Dr. Ellison said that it had been agreed that the transfer of a patient from one hospital to another would in no way prejudice his rights.

Dr. Ellison moved the acceptance of the report. This motion was seconded by Dr. Munro, and it was so ordered by vote of the Council. (Dr. Ellison left the rostrum amid applause.)

Subcommittee on Postpayment Medical Care (Bank Plan) — Dr. Elmer S. Bagnall, Essex North, chairman.

Dr. Bagnall reported as follows:

I crave your leave to give you an informal report progress, because we had a meeting only this afternoon with Mr. McCarthy, of the National Shawmut Bank, who has sponsored this plan in Massachusetts for the Massachusetts Bankers Association.

Mr. McCarthy has been to New York to consult with the American Bankers Association, which has been very much interested in this plan — so much so, in fact that it is going to spend several thousand dollars in working this thing out in Massachusetts as a guinea-pig state.

They have some material, which Dr. Ellison and I looked over this afternoon, with which both of us were very much impressed. They want our endorsement of all of it before it goes through, but I will not take time to rehearse again the steps that have gone before in this bank plan.

I should like to say also that the American Bankers Association and the Massachusetts Bankers Association would like to include the hospitals in this plan, and they are going to contact the Massachusetts Hospital Association, so that there can be a reasonably effectual plan of postpayment medical care, supplementing prepayment medical and hospital care. The dentists will likewise be consulted. This will take care of those people who have not been foresighted enough to provide for their medical and hospital care in advance.

Dr. Bagnall moved the acceptance of this report as one of progress. This motion was seconded by Dr. Hornor, and it was so ordered by vote of the Council.

Committee on Prepayment Medical-Care Costs Insurance — Dr. James C. McCann, Worcester, chairman.

No report.

Dr. Hornor moved the acceptance of the report of the Committee on Public Relations as a whole. This motion was seconded by Dr. Walter G. Phippen, Essex South, and it was so ordered by vote of the Council.

Committee on Cancer — Dr. Ernest L. Hunt, Worcester, chairman.

Dr. Hunt offered the report (Appendix No. 6) by title. In calling the attention of the Council to the fact that the advance sheets contained the report in its entirety, he spoke as follows:

The chairman of this committee would like to express his appreciation for the action of the Council at the last meeting on the question of fees in these clinics. He believes that the action of the Council was a great help in enabling the committee to get together with the State Department of Public Health and bring about a change in the rules and regulations, which has eliminated the cause of the complaint that was registered at the last meeting.

The report of the committee is found on page 8 of the preprint, and should be modified to this extent, that the one member who was absent from the committee at the time the report was adopted, has signified, in writing, his approval of the report, which makes it unanimous.

There is the formal report appearing on pages 8 and 9 of the advance sheets, and there is included a copy of the rules and regulations as revised, and made official by action of the Public Health Council as of April 11, 1944.

The essential point in the modification of the rules and regulations, which is a concession, I think, and a very happy one, is found on page 11 and is Plan C, which reads:

This plan is somewhat similar to Plan A. All patients seeking consultation service are examined at the clinic and receive advice irrespective of their financial

status, but the Commonwealth is only billed for "such persons as may be in whole or in part unable to support or care for themselves" and no fee is collected from any individual.

That is satisfactory to the committee, and the committee recommends that the report be accepted, and that the Council express its approval of the revised rules and regulations as here submitted.

Dr. Charles C. Lund, Suffolk, moved acceptance of the report. This motion was seconded by Dr. Walter H. Pulsifer, Plymouth, and it was so ordered by vote of the committee.

Dr. Lund moved the approval of the rules and regulations of the State Department of Public Health in the conduct of the state-aided cancer clinics, as revised by the Department on April 11, 1944. This motion was seconded by Dr. Hornor, and it was so ordered by vote of the Council.

War Participation Committee — Dr. William B. Breed, Suffolk, chairman.

This report, which was presented by the co-chairman, Dr. Ralph R. Stratton, is as follows:

The work of the committee has been admirably covered by Doctor Breed, the chairman, in his reports to the Council on October 6, 1943, and February 2, 1944. At the close of the last report Doctor Breed said:

The War Participation Committee believes that definite steps should be taken throughout the Commonwealth to devise methods to meet possible emergency medical needs in the event of a serious epidemic and will proceed to instruct the district war participation committees along the lines that are finally decided on, be it through hospitals, through district headquarters or by means of a combined plan, flexible enough to fit the needs of differing local conditions.

Subsequent to the February meeting the committee has taken steps to bring this about. A dinner meeting was held on March 1, to which the presidents of the eighteen district societies and the chairmen of the district war participation committees were invited. The attendance, although not 100 per cent, was very gratifying to the committee.

After the opening remarks by the chairman anent the subject under discussion, a free discussion was indulged in by all the members present. A motion was passed that the chairman of the central committee write a letter to the chairmen of all district committees asking them to call this matter to the attention of their district societies at their annual meetings and to send reports to Doctor Breed by May 1. This instruction was carried out and a fair response was received from the district committees.

A thorough study was made of the stenotype report of the dinner meeting and of the letters received. This study has resulted in the following conclusions:

(1) That under ordinary conditions all portions of the Commonwealth are adequately protected by medical personnel.

(2) That a mild epidemic could be covered by the existing medical manpower without undue hardship either to the profession or to the public.

(3) That in a severe epidemic, in spite of a shortage of medical manpower and of trained nurses and the lack of adequate hospital conditions, most of the material needs of the people could be met by an appeal to:

(a) The American Red Cross, which, through its Disaster Committee, is in a position to give immediate aid with housing facilities, food, clothing and beds, and a satisfactory number of nurses' aides; and to

(b) The local defense boards which, by their setup, can augment the work of the Red Cross.

(4) That in a critical shortage of medical manpower in any locality due to a severe epidemic, an appeal could be made successfully to the Medical Division of the Massachusetts Commission of Public Safety.

A cordial working agreement to this effect has been reached between the War Participation Committee of the Massachusetts Medical Society, the American Red Cross and the Massachusetts Committee of Public Safety.

Dr. Stratton moved the acceptance of the report. This motion was seconded by Dr. Bearse, and it was so ordered by vote of the Council.

Dr. Stratton moved that the report be publicized. This motion was seconded by Dr. Frank W. Snow, Essex North, and it was so ordered by vote of the Council.

Rehabilitation Committee — Dr. William E. Browne, Suffolk, chairman.

This report, which was offered by Dr. Browne, is as follows:

Your committee met once since the last meeting of the Council was held in February.

At this meeting Dr. Wilinsky discussed some phases of the rehabilitation program in this state. Mr. Louis M. Tracey, representing Mr. Herbert A. Dallas, supervisor of the Rehabilitation Section under the Commissioner of Education, outlined a contemplated program that will be based to a considerable extent on regulations governing the plans and program of vocational rehabilitation issued by the Federal Security Administrator during the last of the year 1943.

Mr. Dallas indicated that, when plans are completed for operation of this program, the members of the Massachusetts Medical Society can be of great assistance. Until we hear further from Mr. Dallas, under whose immediate supervision this program will be put into effect, no action by the committee seems necessary.

Dr. Browne moved the acceptance of the report. This motion was seconded by Dr. Phippen, and it was so ordered by vote of the Council.

Committee on Postwar Loan Fund — Dr. George L. Schadt, Hampden, chairman.

Dr. Schadt read the report (Appendix No. 7) in its entirety. He moved the acceptance of the report. This motion was seconded by Dr. Peirce H. Leavitt, Plymouth.

Dr. Ellison spoke of the young doctors who had gone into the armed service immediately on the completion of their internship. Many of these young men, he added, were eligible for membership in the Massachusetts Medical Society. He asked if some arrangement could not be made whereby these young men might participate in the benefits of the plan.

Dr. Schadt replied that such an arrangement might be worked out at future meetings of the committee.

The motion was adopted by vote of the Council.

Dr. Schadt moved the immediate adoption of the recommendations contained in the report and the placing of this plan in immediate operation. This motion was seconded by Dr. Leavitt.

Dr. Munro was recognized by the chair and spoke as follows:

It seems to me that there was considerable doubt in the Executive Committee of the Council whether or not there had been sufficient distribution of the data in this report among the various district societies. At the meet-

ing of the Executive Committee there were many representatives from various districts who thought that they themselves and their members were not sufficiently familiar with the implications of this report to accept the recommendations at this time, in other words, they believed that an opportunity should be given to spread the contents of this report among the individual members of the various district societies.

Dr. Munro moved as an amendment that the recommendations of the Executive Committee with regard to this report be adopted. This motion was seconded by Dr. Leroy E. Parkins, Suffolk.

The Secretary, at the request of Dr. Lee, read these latter recommendations as follows:

The Executive Committee recommends, with regard to the report of the Committee on Postwar Loan Fund, that this matter be laid on the table until the Council meeting in February, 1945, so as to afford time for its discussion by the district societies, and opportunity for the members of the Society as a whole to express themselves on it through a return postal-card survey.

Dr. Leavitt thought that action should not be postponed, as recommended by the Executive Committee. He added that the doctors whom it was expected this fund might help were already returning and that the proposals had already been publicized in the *Journal* so that all those who would have to vote on this matter ought to be thoroughly conversant with the subject.

Dr. Ellison asked how the provisions of the G. I. Bill of Rights might affect judgment in this matter.

Dr. Hyman Morrison, Norfolk, said that the Norfolk District Medical Society recommended the adoption of the recommendations contained in the report of the Committee on Postwar Loan Fund.

Dr. Hornor, while approving the recommendations contained in this report, expressed some apprehension concerning the effect that their adoption might have on the nonprofit status of the Society. Dr. Schadt replied that this phase of the subject had been investigated by him and that the Commission of Banks had informed him that our status would not be affected by it.

Dr. Guy L. Richardson, Essex North, spoke as follows:

It is the path of least resistance to pass this thing without the amendment, but in most instances it means doubling the dues. I should like to have each member of the Society in each district given the opportunity to acquiesce to this thing, as I believe practically all of them will. I do not believe that the delay until February will seriously inconvenience anyone. I am personally in favor of Dr. Munro's amendment, and I am certainly in favor of Dr. Schadt's committee's report, but I should like to see it go that way.

Dr. Chapin thought the Council should defeat the amendment and adopt Dr. Schadt's motion. He asked if it were not true that the members could be assessed to the extent provided in the report but that they did not have to pay it. Dr. Schadt replied that any assessment levied by the Society is an obligation that must be met by the individual if his membership in the Society is to continue.

Dr. Bearse said that if the Council approved amendment, it did not mean that it disapproved recommendations contained in the report. All meant was that certain additional steps should be taken to find out the viewpoint of the members at large. He expressed approval of the amendment.

Dr. Parkins spoke as follows:

I wish to take up the line of reasoning of Dr. Bearse. I am in favor of helping anybody who needs help, any who has participated in this war, but I do not think any of us can be accused of being unpatriotic or stingy, thinking this over.

From the treasurer of the Society I learned that we have \$165,000 lying idle in treasury at the present time. I want yet to have anybody answer what those funds are being held for. It seems to me reasonable that we pursue thought, What are we proposing to appropriate funds? We propose to help men. What for? To borrow money they will pay back. What for? To go into the treasury of the Massachusetts Medical Society—\$150,000, out of \$165,000, or a total of over \$300,000. What are we going to use that for? I should like to know what answer is.

I am very much in favor of postponing the final action until the February meeting, not with any idea of being stingy or unpatriotic. No one can accuse any of us of that because we are in favor of this amendment.

Dr. Munro said that he personally favored adoption of the recommendations contained in the report. He pointed out, however, that when the report was before the Executive Committee for review, it provoked a good deal of discussion as to whether or not the members at large would favor the recommendations. It was thought best to find out about that before proceeding.

Dr. J. Harper Blaisdell, Middlesex East, asked how many cases now exist that need the type of help provided for in the recommendations contained in the report. Dr. Schadt replied that he did not know.

Dr. Fitz spoke to the question asked by Dr. Ellison, which had not been answered and which concerned the young doctor now in service who is not a member of the Society. He asked if there was any way in which the young man might be included. Dr. Schadt replied that he would like to see this done and that he thought it could be worked out.

Dr. Lee put the amendment. It was so ordered by vote (show of hands) of the Council.

Dr. Leavitt moved that the Society appropriate \$20,000 out of the \$150,000 that had been talked about to be turned over to the committee for working basis until February, provided that, if at that time the assessment went through, the money would be returned. Dr. Leavitt expressed some apprehension whether or not this motion was in order. The motion was not seconded.

Military Postgraduate Committee—Dr. W. Richardson Ohler, Norfolk, chairman.

The report, which is as follows, was offered by Dr. Ohler:

In the report presented to this body at the midwinter meeting, it was stated that the object of this program has been officially declared to be an effort to present the best medical knowledge on the respective subjects from the point of view of civilian medical practice. Attention was also directed in our previous report to the fact that this work represents a co-operative effort of the various New England state medical societies, the American Medical Association, the American College of Physicians and the American College of Surgeons, on the one hand, and the United States Army, Navy and Coast Guard, on the other.

Since the meeting in February, the work of your committee has progressed with an ever-increasing degree of co-operation on the part of all the organizations involved and with what we believe to be an increasing sense of appreciation from the various Army, Navy and Coast Guard installations served by this program.

In February, it was reported that fifty-five exercises had been held in nineteen military installations scattered throughout New England. Since February, another installation has been added to the group, and seventy-six exercises have been presented. This makes a total for the year of one hundred and thirty one exercises in twenty military installations.

That this work has received the whole-hearted co-operation of the officers of the Army, the Navy and the Coast Guard is attested by recent letters, brief extracts from which I shall now read.

Such a program cannot fail to have its effect in improving the professional standards everywhere, but I wish to emphasize the vital importance of this program at the smaller stations where the staff is limited. At these somewhat isolated stations, particularly, the stimulus provided by your meetings has been especially appreciated both locally and by this headquarters. J. J. Reedy, Col., M.C., U.S.A.

I wish to take this occasion to express our appreciation for the work involved in this effort on the part of your committee and on the part of the eminent lecturers who have given of their time and substance. I think all will agree that it has been a great success and of special value to the small and isolated stations where medical contacts are difficult to obtain. R. H. Laning, Rear Admiral (MC), U.S.N.

We all feel that it has been a distinct contribution to the war effort, and I speak for the medical officers when I say that we have all felt that we have benefited greatly from such conferences. It is my hope that these programs will continue so long as the war continues. Charles J. McDevitt, Senior Surgeon, U.S.P.H.S.

The success of this work is due to the splendid co-operative effort of all concerned. It is my particular pleasure at this time to speak very highly of the unselfish attitude of all the instructors, many of whom have been forced to give up a good deal of time in order to reach some of the isolated stations. Without the enthusiastic response by this group of doctors, the work could not continue.

Finally, it has been requested by the chiefs of all the military organizations involved that programs continue throughout the summer months.

Dr. Ohler moved the acceptance of the report. This motion was seconded by Dr. Hall, and it was so ordered by vote of the Council.

Medical Advisory Committee to Regional OPA — Dr. Joseph Garland, Suffolk, chairman.

This report, which is as follows, was offered by Dr. Garland:

The records of this committee, which now cover ten months' work, indicate that 2382 applications for extra rations have been referred by the local boards to the Regional Office of the OPA. Of these 1658 have been granted in some part, and 727 have been denied. Members of the committee reviewed 963, or 41 per cent, of the cases.

During the year the district served was enlarged to include the entire state, and was then merged with the Regional Office, covering all of New England. Since Rhode Island has been the only other state with a medical advisory committee, the services of your committee have been utilized to aid in solving the rationing problems of the remainder of New England, which for the past month have numbered 131. The other state societies have been requested to appoint similar committees, and it is expected that this will be done at their annual meetings.

The recommendations of the Subcommittee on Medical Food Requirements of the National Research Council, published in October, were adopted by the national Office of Price Administration in March, and have been used as a basis for the decisions of your committee. The policy of the national office, however, as recently expressed, is to let the administration of the medical programs revert to the regional offices.

Frequent changes in point values have increased the task of trying to deal fairly with all applicants, and emphasize the necessity for a flexible program. The recent change to zero point values for all except certain choice cuts of meat has added particularly to the perplexities of the problem, since those who now request extra meat rations are obviously seeking luxury rather than medical-necessity diets. Many fantastic requests continue to be made, and more are referred to the Regional Office than formerly, as the local boards have been more limited in their scope of action.

The work of the committee has been greatly facilitated by the intelligent and efficient co-operation of Miss Elizabeth Golden, rationing aide to the Regional Office.

Dr. Garland moved the acceptance of the report. This motion was seconded by Dr. Maurice Fremont-Smith, Suffolk, and it was so ordered by vote of the Council.

In connection with this report, Dr. Lee said that comment in Washington had it that the work of the Massachusetts Medical Advisory Committee to the Regional Office of the OPA was far and away the best in the country.

Committee Appointed to Consult with Representatives of the New England State Medical Societies Regarding the Wagner-Murray-Dingell Bills — Dr. Walter G. Phippen, Essex South, chairman.

Dr. Phippen said that the committee had no report to offer and, inasmuch as the work of the committee had been finished, he moved its discharge. This motion was seconded by Dr. Hall, and it was so ordered by vote of the Council. (Dr. Phippen was applauded as he left the platform.)

Committee on Medical Information Bureau — Dr. Walter G. Phippen, Essex South, chairman.

Dr. Phippen reported as follows:

Your committee has considered the advisability of establishing a bureau of information at the Society's headquarters with considerable care. We have investigated and studied the bureaus that have been operating for many years in New York City and Philadelphia. Although the methods of operation of these bureaus differ in detail, their main object is the same, that is, to collect information from the various hospitals regarding operations, clinics, meetings and so forth, in one central place so that it may be readily available. Both these bureaus have been very successful and are evidently much appreciated by visiting physicians, as well as by local practitioners.

We were convinced of the need here in Massachusetts of such a bureau but before recommending it to the Council

thought that it would be helpful to try and get an opinion from the members of the Society. You have all received the prospectus, and many of you have returned the cards. The results of the poll have been quite illuminating. Up to the time of writing this report 908 replies have been received. Of these, 849 (about 95 per cent) have approved and 46 have disapproved; there were 13 blanks. Such a spontaneous reply speaks for itself. Some members wrote accompanying letters favoring the idea in more detail. One interesting card came from a doctor in Vermont who said that, although he was not a member of the Massachusetts Medical Society, he thought that such a bureau was very much needed and would be very helpful to visitors. Most of those who disapproved seemed to have a mistaken idea that it would benefit only those in the Metropolitan Area, whereas it is primarily for visitors from all over the Commonwealth, and to aid those returning from service with the armed forces to find easily the graduate instruction they will need.

This bureau will supply information concerning the daily activities of the Boston hospitals and of other hospitals in the immediate vicinity of Boston. This information will deal with each hospital's schedules of operations for the day, medical and surgical ward rounds, clinics, the location of such clinics and the names of those presiding over these various activities. From time to time the bureau will make available a bulletin that will list fixed medical meetings and conferences held in the Metropolitan Area. In brief, its ultimate aim will be to serve the profession as a clearing house for all sorts of medical information. It is proposed to disseminate this information, except that contained in the bulletin, by telephone. With this end in mind, the headquarters will be kept open such hours as will meet with the needs of the busy practitioner.

The committee makes the following recommendations:

- (1) That a Bureau of Information be established at the headquarters of the Massachusetts Medical Society, 8 Fenway, Boston.
- (2) That the committee authorized by the Council and appointed by the President to study the subject be authorized to supervise its installation.
- (3) That an appropriation not to exceed \$2500 be made for this purpose.

Dr. Phippen moved the acceptance of the report. This motion was seconded by Dr. Cheever, and it was so ordered by vote of the Council.

Dr. Phippen moved the adoption of the recommendations contained in the report. This motion was seconded by Dr. Hall.

Dr. Parkins asked what the \$2500 would be used for. Dr. Phippen replied that it would be used for a separate telephone line, additional clerical service, stationery, postage and expenses incidental to getting out the bulletin.

Dr. Leavitt asked if this was going to be an annual appropriation. Dr. Phippen replied that this amount was only for the first year and that the committee did not know what it would cost annually until it had been tried out.

The recommendations were adopted by vote of the Council. (This action was greeted with applause.)

Committee to Meet with the Trustees of Middlesex University — Dr. Reginald Fitz, Suffolk, chairman.

This report was offered by Dr. Fitz. Subsequently, Dr. Fitz moved that the report of the committee, the discussion attending it and the vote of the Council concerning it be stricken from the record. This motion was seconded by Dr. Charles E. Mon-

gan, Middlesex South, and it was so ordered by vote of the Council.

Committee on Postgraduate Instruction — Dr. Reginald Fitz, Suffolk, chairman.

No report.

Committee on Physical Therapy — Dr. Arthur L. Watkins, Middlesex South, chairman.

No report.

Committee to Consider Expert Testimony — Dr. Frank R. Ober, Suffolk, chairman.

No report.

Committee on Automobile Insurance Claims — Dr. Henry C. Marble, Suffolk, chairman.

No report.

Committee to Study the Practice of Medicine by Unregistered Persons — Dr. Richard Dutton, Middlesex East, chairman.

No report.

Committee to Meet with the Massachusetts Hospital Association — Dr. Walter G. Phippen, Essex South, chairman.

No report.

Committee on Maternal Welfare — Dr. Judson A. Smith, Suffolk, chairman.

No report.

Committee on Ways and Means to Conserve Physicians' Energies — Dr. Elmer S. Bagnall, Essex North, chairman.

This report, which was offered by Dr. Bagnall, is as follows:

Inasmuch as the subsequent work initiated by the committee has been distributed between the Committee on Public Relations and the Committee on War Participation, we recommend that this be considered the final report and that the committee be discharged by the Council.

Dr. Bagnall moved the acceptance of the report and the discharge of the committee. This motion was seconded by Dr. Hall, and it was so ordered by vote of the Council.

ELECTION OF OFFICERS

Dr. Ralph R. Stratton, Middlesex East, chairman of the Committee on Nominations, reported as follows:

President: Dr. Elmer S. Bagnall, Essex North
Vice-president: Dr. Sumner H. Remick, Middlesex South
President-elect: Dr. Reginald Fitz, Suffolk
Secretary: Dr. Michael A. Tighe, Middlesex North
Treasurer: Dr. Eliot Hubbard, Jr., Middlesex South
Assistant treasurer: Dr. Norman A. Welch, Norfolk
Orator: Dr. Frank H. Lahey, Suffolk

The chair asked if there were any nomination from the floor. Dr. Ober moved that all nomination

closed. This motion was seconded by Dr. Phippen, and it was so ordered by vote of the Council.

Dr. Stratton moved that the Secretary cast one ballot for the list of nominations as read. This motion was seconded by Dr. Paul J. Jakmauh, Norfolk, and it was so ordered by vote of the Council.

The Secretary announced that he had complied with his directive, and the President declared the officers elected. (Dr. Lee introduced each of the elected officers, except Dr. Lahey, who was not present, to the Council. They were greeted with applause.)

APPOINTMENT OF COMMITTEES

Dr. Elmer S. Bagnall, Essex North, president-elect, announced the committee nominations for 1944-1945. (The list will be published with the proceedings of the Society in a subsequent issue of the *Journal*.)

In making these appointments, Dr. Bagnall called to the attention of the chairmen of the various committees the provision in the by-laws that makes the president and president-elect members of all committees, and said that they should be notified of all meetings.

He added that there was a question whether or not some of these committees had finished their work. He pointed out that certain committees had not reported for a number of years and have no apparent activity. He said the by-laws require that each committee report in writing at least annually. He expressed the thought that the Society's slate might be cleared a little if some of these inactive committees could be taken care of by the Executive Committee.

Dr. Mongan, in arising for information, said that the President-Elect had appointed a committee to confer with the trustees of Middlesex University Medical School and that it was his understanding that the Council would have no such committee.

Dr. Lee pointed out that this committee had not been discharged. Dr. Mongan moved the discharge of the committee since there was no more work for it to do. This motion was seconded by Dr. Hornor, and it was so ordered by vote of the Council. Dr. Bagnall announced that he withdrew the nominations to this committee.

Dr. Bagnall moved the approval of the nominations made by him. This motion was seconded by Dr. David D. Scannell, Norfolk, and it was so ordered by vote of the Council.

RESOLUTIONS

Dr. Lee read the following obituary of a deceased councilor:

Dr. John J. Cochran, of Natick, died May 1, 1944. He was in his forty-eighth year.

He received his degree from Harvard Medical School in 1923. He was a member of the courtesy staffs at the Newton and Framingham hospitals. He was an examiner for the local Selective Service board and a member of the American Legion and of the Harvard Club of Boston.

Dr. Cochran was also a member of the Council from the Middlesex South District.

His widow, two sons and two brothers survive.

The chair announced that, if there were no objection, the obituary would be spread on the records of the Council.

The chair called for resolutions on the death of Dr. Charles S. Butler, late treasurer of the Society. Dr. William H. Robey, chairman of the Resolutions Committee anent the death of Dr. Butler, said that these resolutions were to be read at the annual meeting of the Society, and that he would not, owing to the lateness of the hour, read them unless the President and Council so desired. The chair announced that, if there were no objection, the resolutions would be spread on the records of the Council without being read.

The resolutions are as follows:

Dr. Charles Shorey Butler was treasurer of the Massachusetts Medical Society from June, 1931, until the time of his death, which occurred on February 23, 1943.

Dr. Butler was born in Boston on July 6, 1870, the son of Charles Shorey Butler and Elizabeth Nancy Cummings. He graduated from Harvard College in 1893 and from the Harvard Medical School in 1897. After an internship at the Massachusetts General Hospital he entered private practice, served on the staff of one of the Boston hospitals and taught anatomy at Harvard. Quite early in his medical life he became interested in military medicine and served for seven years as assistant surgeon in the Massachusetts Volunteer Militia. At the time of his resignation he was a captain and assistant surgeon in the 8th Infantry Regiment. In 1915 he became a surgeon in the French Army, for which he was decorated by the French Government, having been made a chevalier of the Legion of Honor. On his return to this country he was commissioned captain in the Medical Reserve Corps of the United States Army and examined candidates for the Air Corps.

After several years Dr. Butler retired from active practice and teaching but continued to have a keen interest in the medical profession, in military medical work and particularly in strengthening preparedness among physicians in civilian life. He also retained his interest in the Medical Reserve Corps, in which he held the rank of lieutenant colonel.

Dr. Butler had an interest in finance and financial affairs; he liked to study the reports of corporations, and he became a trustee of several estates. As a result of his business interests he was selected for the office of treasurer of the Massachusetts Medical Society, and under his guidance the financial standing of the Society steadily improved. He bought and sold wisely, and his annual reports were received with applause.

Modest and self-effacing, his capabilities were sometimes hidden, but to those who knew him and worked with him, his courage and conscientiousness were ever apparent. He strove constantly to maintain the high ideals of the Massachusetts Medical Society, and his wise counsel will be greatly missed and long remembered by his colleagues.

NEW BUSINESS

Dr. Jacob Fine, Suffolk, was recognized. He said he had been inadvertently detained in getting to the meeting. He asked if it would be appropriate to make a few remarks concerning the report of the Committee on Membership. Dr. Schadt moved that Dr. Fine be given the privilege of the floor. This motion was seconded by Dr. Hall, and it was so ordered by vote of the Council.

Dr. Fine read a statement (Appendix No. 8) to the Council.

He moved the five-year exclusion provision adopted in 1942 as an amendment to the by-laws be submitted to the Council at its next meeting for further consideration, with a view to its revocation. This motion was seconded by Dr. Lund.

The question of a quorum was raised; 53 councilors were present. Dr. Lee announced a quorum present. The issue of a quorum again being raised and a quorum not being present, Dr. Fine withdrew his motion.

Following a motion by a councilor and a second by another councilor, the Council voted to adjourn at 11:15 p.m.

MICHAEL A. TIGHE, *Secretary*

PPENDIX NO. 2

REPORT OF THE COMMITTEE ON MEMBERSHIP (AND SUPERVISING CENSORS)

The following motion, offered by Dr. Jacob Fine, was passed by vote of the Council on February 2, 1944:

I move that the Committee on Membership be instructed to reinvestigate the merits of the five-year exclusion provision of the recent amendment with a view to reducing the time after a license is granted before membership in the Society is permissible.

This motion was preceded by a statement by Dr. Fine, which is hereby appended.

The Council may be interested in certain data regarding the foreign physicians licensed in Massachusetts. According to the *American Medical Directory* and the files of the Boston Committee on Medical

FIGURE 1. Results of Examinations by the Massachusetts Board of Registration in Medicine of Graduates of Foreign Medical Schools.

Emigres, a total of 165 foreign physicians have been licensed to practice in this state since 1934. The Committee on Medical Emigres has data in its files on all but 35 of the total number—that is, it knows the type of activity and the location of settlement of 130 of them. They are distributed as follows: 40 hold institutional positions exclusively, 66 practice a specialty or are in general practice in large or medium-sized cities, and 23 practice in small towns. They are settled in all parts of the State. Of the total number, 72 are members of the Society and 92 have not been admitted.

With these facts in mind, the following questions present themselves:

(1) Have any of the 72 foreign physicians who are members of the Society and who became members before the amendment to the by-laws was adopted acted unethically? Have any of them acted so as to prejudice the interests of the Society, their fellow practitioners or the profession at large?

(2) Of the 92 foreign physicians who are not members of the Society, all but 5 have been licensed for two or more years. Twenty-four hold institutional positions; 68 are in various specialties and general practice. Of this group of 68, have any acted during these two or more years in such a way as to prejudice the interests of their fellow practitioners or the profession at large?

The Committee on Medical Emigres has received complaints in three instances: in one case it could not get sufficient information; in a second, in which the physician was undesirably publicized in a newspaper shortly after his settlement, there was evidence that the physician was taken in by an overzealous young lady reporter apparently anxious to get material; and in the third case, now under investigation, the evidence is incomplete and conflicting, but the weight of evidence from the community itself is overwhelmingly in the physician's favor.

Rumors, vague accusations and generalizations regarding the demerits of these foreign physicians have been numerous, but specific demonstrable incidents of unacceptable practices have been exceedingly scarce and not out of proportion to what we experience among native-born physicians.

At the annual meeting in May, 1942, 44 per cent of those voting on the amendment to the by-law disapproved it. The Committee on Medical Education unanimously disapproved it. The machinery for excluding undesirable physicians from the Society existed before the amendment was adopted.

What experience did the Society or the profession have before or since the adoption of the amendment that justifies its continuance in its present form? The threat of inundation of the State by foreign physicians was never real, and today there is only a rare individual who might settle here, even if he were encouraged to do so.

It therefore seems appropriate for the Council to consider whether or not the amendment to the by-law is unnecessarily restrictive in its five-year exclusion provision.

At the beginning, Dr. Fine states that "according to the *American Medical Directory* and the files of the Boston Committee on Medical Emigres a total of 165 foreign physicians were licensed to practice in this state since 1934." When an applicant passes the examination of the Massachusetts Board of Registration in Medicine, he automatically becomes registered and licensed in this state. Information from the Board shows that in a six-year period (1938 to 1943, inclusive), 309 applicants who were graduates of foreign schools passed the examination of the Board, and 404 failed. This figure of 309 successful applicants between 1938 and 1943 is quite different from Dr. Fine's figure of 165 licensed men since 1934. This marked discrepancy of facts makes it difficult to evaluate the remainder of his statement.

I. For a true understanding of this problem, and particularly to see if the present by-law incorporating the five-year waiting rule for applicants of foreign schools was a departure from long-established custom in the Massachusetts Medical Society, it seems wise to review the history of the Society in relation to this by-law.

From studying the old by-laws it is apparent that the Society has attempted since its beginning to maintain high standards in the election of foreigners. It was in 1816 that the election of persons "educated without the Commonwealth" first arose. Such physicians might be eligible for membership if they had studied three full years under the direction of some reputable physician or surgeon or—as was said in 1832—if they had followed in their medical studies a course equivalent to that pursued by eligible candidates from Massachusetts.

This general policy was maintained for many years; in 1913, each candidate must have received a diploma from a medical school or college recognized by the Council and must also have passed the ordinary examinations, it being left entirely to the Committee on Medical Education and Medical

FIGURE 2. Results of Examinations by Censors of the Massachusetts Medical Society of Graduates of Foreign Medical Schools.

Diplomas to determine what foreign schools could be accepted as offering an education equivalent to that of our recognized domestic schools.

This procedure operated fairly well until an increasing number of foreign-trained physicians began to infiltrate Massachusetts. No one knew how good an education such people had received. I am informed by the chairman of the Committee on Medical Education that an evaluation of medical education in foreign schools, particularly that gained on the Continent, is almost impossible. Further, it is well known, particularly in Germany and Italy, that medical students may attend four or even five universities during

their medical course, taking their degree from the last attended university. Apparently the practice of a student transferring himself from different universities in order to study a particular science under a well-known leader in that field is not only generally practiced but also encouraged. Thus in 1939 the by-laws were rewritten to require that a graduate from a foreign medical school, to be eligible for membership, must have practiced for a minimum of five years and be recommended by a number of his colleagues who were fellows.

The expression "must have practiced for a minimum of five years" was evidently purposely loose: it might mean practice anywhere—indeed including internship as practice—or might be interpreted to mean a minimum of five actual years of practice within the confines of Massachusetts. This was done so that the Committee on Medical Education and Medical Diplomas might interpret the five-

III. There can be no question that there will be an additional foreign-educated physician on whom the five-year will work a hardship. The committee believes these cases rare. Outstanding physicians can be recommended by the Society for consideration for associate membership, thus become fellows of the Society in an honorary capacity without right to hold office or vote. Some physicians with American citizens have been educated in foreign medical schools. In a great many instances, if not in a large percentage of this group, inability to become a fellow of the Massachusetts Medical Society has not in the slightest hampered physicians from holding hospital appointments and continuing on an active practice in this state following licensure. It is well known that a great many of the best hospital staffs in this state admit substandard and foreign medical graduates to their courtesy staffs and allow them to treat their patients there, often without supervision of

FIGURE 3. Applicants for and Admissions to Membership in the Massachusetts Medical Society Classified according to School of Graduation.

year wording as seemed best, admitting easily certain foreign trained physicians of assured reputability but holding back less well-known emigres from schools about which little was available.

Finally revised and accepted in May, 1942, the by-laws were clarified. It was voted that the diploma from a graduate of a foreign medical school be not approved unless he had possessed for at least five years a license to practice medicine in the United States or its territories.

It is, therefore, clear that there has been no departure of principle of the Society in the present by-law but only one of clarification of it, and that a considerable waiting period has been deemed advisable by this society before allowing applicants who are graduates of foreign medical schools to become fellows.

II. According to information from the Massachusetts Board of Registration in Medicine, beginning with 1939, all foreign-educated physicians must become citizens of the United States or have their registrations in this state revoked at the end of five years. It seems to the Committee on Membership that citizenship in the United States should be mandatory for fellowship in the Massachusetts Medical Society. It therefore seems clear that from this point of fact the five-year rule is necessary as it now stands.

physicians; and even with supervision, the testing period is short. On this point, therefore, membership in the Massachusetts Medical Society is not tantamount to for foreign educated physicians to allow them full scope in the practice of medicine in this state.

IV. Investigation of the medical caliber of graduates of foreign medical schools seemed advisable to the committee. In Figure 1 are shown the number of such applicants in each year from 1938 to 1943 who passed and failed the examinations by the Massachusetts Board of Registration in Medicine. The total figures are 309 passed and 403 failed. Of interest in this chart is that the greatest number of passed and registered applicants was in 1940, when 120 men were licensed. This group will be eligible under the present laws to become fellows of the Society within about a year or in approximately the same length of time necessary to alter or change the present by-law. Since 1940 it is obvious that there has been a steady decline in the number of foreign graduates passing the state-board examinations and therefore this rule should not be a great hardship.

It was also of interest to the committee to chart the experience of the Massachusetts Medical Society with graduates of foreign medical schools, taking as the index the censors' examinations for membership between 1938

1945 (Fig. 2). Again, in the last two years the number applicants has steadily fallen. In both Figures 1 and 2 to be noted that the ratio between passed and failed in class of applicants does not indicate a particularly high of medical education. This is further borne out by re 3, which charts this same ratio between number of applicants and number of applicants passed for fellowship the Massachusetts Medical Society in our three classifications. At the top is charted the curve between 1938 and 1945, inclusive, of graduates of approved United States schools. This graph indicates a high level of medical educational standards. The two lower pairs of curves represent, applicants of unapproved domestic schools and, second, applicants of foreign schools. Again, the ratio in these two groups between number of applicants and number passing the censors' examinations of the Massachusetts Medical Society shows quite a wide spread, unlike that of the approved schools, and a picture quite similar to each other. These groups of the unapproved domestic schools and graduates of foreign schools do not indicate a high level of medical educational standards.

* * *

To summarize, the Committee on Membership, through study of the history of the by-laws of the Massachusetts Medical Society, finds no departure of principle of the society in the present by-law, but only a clarification of it. It believes that a fellow of the Massachusetts Medical Society could be a citizen of the United States and a five-year period necessary in the case of foreign-born physicians to gain citizenship. Failing to become a citizen of the United States after licensure by this state means a mandatory revocation of license. The committee finds that foreign medical-school graduates as well as unapproved domestic-school graduates are allowed to practice medicine by the large percentage of hospitals, such privilege being a decision of the individual hospital trustees. Membership in the Massachusetts Medical Society is neither mandatory nor necessary for such hospital-practicing privilege. The committee also finds through study of the number of applicants of foreign medical-school graduates and graduates of unapproved domestic schools able to pass the examinations of the Massachusetts Board of Registration in Medicine and the censors' examinations of the Massachusetts Medical Society between 1938 and 1945, inclusive, that these substandard applicants show a markedly lower level of medical education than that of approved medical-school candidates for both of these examinations.

It is, therefore, the unanimous vote and recommendation of the Committee on Membership that the present by-law of the Massachusetts Medical Society, Chapter V, Section 2(b), remain unchanged.

APPENDIX NO. 3

REPORT OF THE COMMITTEE ON INDUSTRIAL HEALTH

The Committee on Industrial Health has continued to work in close co-operation with the State Department of Public Health and with the Division of Occupational Hygiene of the State Department of Labor and Industries. In addition, your committee has been in contact with the Massachusetts Committee on Public Safety, the Massachusetts Safety Council, the Associated Industries of Massachusetts, the New England Conference of Industrial Physicians, the American College of Surgeons, the State Procurement and Assignment Service, and the Council on Industrial Health of the American Medical Association. Two members of the committee attended the annual meeting of the Council on Industrial Health of the American Medical Association, held in Chicago on February 14, 15 and 16.

The committee has kept up to date its register of physicians who might be interested in practicing industrial medicine.

The supply of physicians available for industrial medical service in Massachusetts continues in excess of the demand, however, and we have not succeeded in making more than a dozen placements during the year and a half that the register has been in operation. Of the original three hundred odd who registered with us, more than a third have requested, for various reasons, that their names be removed from the list. A few names have been added, but on the whole our experience has demonstrated that industrial health in Massachusetts does not lag for lack of medical placement. It is good to know that in these days of social shortages, some of which are being hung at the door of organized medicine.

Last fall the committee prepared a third industrial-health program, to be presented in Springfield. It was to have been similar to those previously held in Boston, but had to be canceled because a suitable meeting place could not be secured and also because the committee could not get evidence of sufficient local interest to support it.

During the winter the attention of the committee was directed to federal legislation calling for appropriations to state departments of labor for industrial health. We unanimously voted our emphatic disapproval of such appropriations, on the ground that matters of health should be administered by health departments, and that there should not be initiated in labor departments a duplication of work already well developed in most states by their health departments. Your committee considered that this was an important legislative matter, and was pleased to learn that the chairman of the Committee on Legislation was in hearty agreement with this opinion. With his knowledge, we communicated our views to the representatives from the Commonwealth of Massachusetts in Washington.

In its report on October 7, 1942, this committee stated that it was "most perplexed to know how to reach . . . those who are employed . . . in the small plants that are now rushing war production." The fact that three quarters of the workers are so employed gave this problem great urgency. It has been obviously impossible for the small plant to establish a real medical department, and it has been difficult for many of them to feel justified in employing full-time nurses; yet over the country as a whole the small plants were and still are providing the largest part of the industrial hazard to which our workers are exposed. A promising approach to this problem in Massachusetts has now been made by the activities of those who variously call themselves district nurses, visiting nurses or community-health nurses. Several of these groups in Massachusetts have already developed sufficient insight into industrial needs to offer a special part-time service to the small plants in their areas. These specialized services are now well beyond the experimental stage. They have been called to the attention of the industrialists,* and have so interested the Council on Industrial Health of the American Medical Association that it has signified its intention to visit the places where such services are in operation. In a paper read before the war session of the American College of Surgeons in Springfield on March 20, the plan was presented from the practitioner's point of view, and it was urged that physicians assume leadership in its future development; this paper is scheduled for publication in the June 8 issue of the *Journal*.

Throughout the Nation, both capital and labor have largely abated their traditional strife over hours and wages. But the striving continues and is frequently expressed in attempts to secure better working and living conditions, in the establishment of health services and benefits for employees, and in many things concerning which sound medical advice is pertinent and should be available. There has been created, in this period of unprecedented industrial activity, a somewhat artificial interest, which is above and beyond normal and valid interest in the promotion of industrial health. We should take advantage of this; the iron is hot, and now is the time to shape it. Industrial health can now be guided and established in plants where it was never thought of before and where, in the years to come, it may be difficult for it to gain another foothold.

The writer of this report regrets that time has not permitted him to submit it to his committee members. It contains no recommendations, and is respectfully presented as a report of continuing progress.

DWIGHT O'HARA, *Chairman*

physicians; and even with supervision, the testing period short. On this point, therefore, membership in the Massachusetts Medical Society is not tantamount to foreign educated physicians to allow them full scope in the practice of medicine in this state.

IV. Investigation of the medical caliber of graduates from foreign medical schools seemed advisable to the committee. In Figure 1 are shown the number of such applicants in each year from 1938 to 1943 who passed and failed the examinations by the Massachusetts Board of Registration in Medicine. The total figures are 309 passed and 403 failed. The interest in this chart is that the greatest number of passed and registered applicants was in 1940, when 120 men were licensed. This group will be eligible under the present by-laws to become fellows of the Society within about a year or in approximately the same length of time necessary to alter or change the present by-law. Since 1940 it is obvious that there has been a steady decline in the number of foreign graduates passing the state-board examinations and therefore this rule should not be a great hardship.

It was also of interest to the committee to chart the experience of the Massachusetts Medical Society with the graduates of foreign medical schools, taking as the index the censors' examinations for membership between 1938

is also agreed that the injured employee, if conscious, be offered two lists of physicians, — one a list of staff ors selected by the insurer and the other a complete list of the members of the hospital staff, including the courtesy list, — with the understanding that the employee has a free choice of any doctor on either of these lists. On the other hand, should the injured employee choose as his physician a doctor connected with some hospital other than the one in which he has been taken he may be removed without prejudice to that hospital, where the physician of his choice will care for him, provided that the other hospital is capable of rendering adequate care.

Your committee believes that it is impossible to prevent a certain number of these patients being taken to unaccepted hospitals and being cared for by men of limited ability, but that the solution of this part of the problem lies in an educational program designed to teach people the difference between recognized and unrecognized hospitals. The problem is not so simple as it seems at this time owing to the absence of many of the best men in the service and to the fact that in our places have been taken by men of considerably less ability in judgment.

There is one other arrangement that has recently been included that in some cases may obviate this difficulty. Through an agreement with the Blue Cross, an injured employee insured under the Blue Cross may be transferred from a ward to a semiprivate or private room and the difference in expense will be paid by the Blue Cross, making such an employee the private patient of the surgeon on duty or of a surgeon chosen by the employee.

It is further thought that freedom of choice of physician of the injured employee should at no time be interfered with. It is the desire of the chairman of the State Industrial Accident Board that a committee of this type be continued.

DANIEL J. ELLISON, *Chairman*

APPENDIX NO. 6

REPORT OF THE COMMITTEE ON CANCER

The Committee on Cancer is able to report substantial progress.

Deeply conscious of its responsibility to the Society and to the victims of cancer dependent on the provisions for diagnosis and treatment maintained for their benefit by the Massachusetts Department of Public Health and encouraged by the action of the Council in its meeting on February 2, 1944, your committee felt impelled to make further efforts looking to an accord with the Department of Public Health in regard to the conduct of its state-aided cancer clinics.

This effort was initiated through the good offices of the president and president-elect of the Society and made possible by the co-operative attitude on the part of the Department of Public Health, as represented by the director of the Division of Adult Hygiene, who accepted an invitation to sit in with the committee at a meeting held in Boston on March 24, 1944.

In a report to the President-Elect, the director had pointed out that a plan for conducting the clinics which does not require the collection of fees from patients able to pay had been worked out for the Beverly Clinic and accepted by the Attorney General's office. This he termed Plan C.

This plan differs from the previous plan, which is now referred to as Plan A, in that it allows any citizen to consult the clinic without charge, but when the Commonwealth is billed for service only those medically indigent are included, since the Constitution does not allow the department to purchase services for other than "such persons as may be in whole or in part unable to support themselves." This results in the clinic receiving less money from the Commonwealth than it would otherwise but meets the objection to the clinic fee of \$10 raised by the Worcester and Beverly clinics, whereas it also sustains the Department of Public Health's policy that no citizen who desires to receive expert advice through group diagnosis by those particularly interested in malignant disease at the clinic can be refused, since they are not held to be ordinary charity clinics but part of a great effort to control such diseases in the public interest.

The director reported that the fees collected from patients in the three months of operation of Plan A have averaged \$2.34 per clinic per month. In the same period the average allotment to clinics from the State Treasury averaged \$213 per clinic per month.

He also explained to the satisfaction of all members present that the sums realized from fees charged patients did not really revert to the State Treasury but were pooled by the department and reallocated to the clinics through increased unit values, for their unrestricted use in maintaining the clinics and furthering the purpose of the clinics and of the cancer-control program.

The Director accepted the suggestion of the committee that the rules and regulations be revised (1) to clarify the paragraph relating to allocation of funds in the manner above explained and (2) to incorporate Plan C and offer it as optional to clinics not wishing to collect fees from persons able to pay but willing to conduct the clinics in all other respects in the manner prescribed by Plan A.

Your committee believes that with the above revisions the rules and regulations confer an added measure of local autonomy on the clinics and will therefore be more adaptable to local conditions while preserving the principle of group consultation service available to all cancer patients, as advocated by the American College of Surgeons, approved by the Department of Public Health and in harmony with the Cancer Law of 1926, as amended in 1943.

The Worcester Cancer Clinic Committee has agreed to accept the terms of Plan C as outlined above.

This committee therefore declares its readiness to recommend that the rules and regulations when so revised and given official sanction by the Public Health Council be approved by the Council of the Society.

Present were Drs. Balch, Simmons, Truesdale and Hunt. The vote was unanimous.

ERNEST L. HUNT, *Chairman*

* * *

The following are the revised regulations referred to in the report of the Committee on Cancer:

THE MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

The Cancer Clinic Regulations approved January 15, 1935, are hereby rescinded and the following substituted

FOREWORD TO CANCER CLINIC REGULATIONS

Whenever possible, all patients shall be referred to the clinic by the family physician, who may supply the clinic with the information requested on the referral card, and who may furnish the clinic with information as to the patient's ability to pay in whole or in part the regular clinic fee.

- 10 Referred patients will be returned for further diagnosis or treatment to the family physician whenever the physician so requests

CANCER CLINIC REGULATIONS

The Massachusetts cancer clinics are of two types: state cancer clinics and state-aided cancer clinics.

- 20 A state cancer clinic is a medical unit furnishing consultation service, diagnosis and treatment for persons suffering from precancerous conditions, suspected cancer, or cancer, "under the exclusive control, order and superintendence" of the State Department of Public Health. This type of clinic at present is held at Pondville and Westfield and could be held elsewhere (Plan B). A clinic under this plan would be administered by the Department of Public Health. The staff would be chosen and salaried by the department. Suitable accommodations, preferably at a hospital, would be selected and paid for by the department. There would be no local autonomy. This method would be expensive and with the present budget only a few clinics could be maintained.

- 30 A state-aided cancer clinic may be defined as a medical unit furnishing either consultation service alone, or consultation service, diagnosis and treatment, for persons suffering from precancerous conditions, suspected cancer, or cancer administered by an organized medical group through a committee, serving without compensation, and from whom the State purchases certain service for the care of "such persons who may be in whole or in part unable to support or care for themselves."

- 40 A committee composed of five or more physicians shall be appointed annually, either by the local medical society or by the staff of a hospital. This committee shall be known as the cancer-clinic committee. The local organized medical group, through its cancer clinic committee, may petition the State Department of Public Health to establish either a state cancer clinic (Plan B) or a state-aided cancer clinic (Plan A, C or D). If a state cancer clinic is requested by the local group and approved by the department, the cancer-clinic committee acts as an advisory body. If a state-aided cancer clinic is requested by the local group and approved by the department, the cancer clinic committee acts as an administrative body. The following rules and regulations apply to the state-aided cancer clinics.

The committee shall be responsible for all administrative matters pertaining to the clinic. These shall include the procurement of suitable quarters for the examination of the patients, preferably in

APPENDIX NO. 4

REPORT OF THE MASSACHUSETTS COMMITTEE ON PROCUREMENT AND ASSIGNMENT

At this meeting of the Council, your committee hoped to be able to close its accounts for the year with a certified statement of its labors. Unfortunately our books do not balance to the last penny, thus the best that we can offer is a description, which admittedly includes certain inaccuracies, of the present state of medical manpower in Massachusetts.

In 1942, the *American Medical Directory* listed 8085 names of doctors residing in Massachusetts. Among those included were practitioners known to be retired and also a number of interns and residents. During 1943 and until now in 1944, the Board of Registration in Medicine has licensed 457 new physicians. Theoretically, therefore, we should be called on to account for a total of 8542. Actually, biographical data have been assembled on 8922 doctors who have been in our midst at some time during the past two years. These names do not include men known to be deceased or retired but comprise physicians believed to have been active here either with temporary registrations or in some more permanent capacity. We always have a large floating medical population because of our reputation as a teaching center, and this probably accounts for the numbers of doctors with whom we have dealt. How many at any one moment were actually at work is not known.

In the group as a whole are 2900 commissioned officers. The studies of the War Participation Committee, as well as our own observations, justify the belief that Massachusetts so far has faced no significant medical shortage and indeed is unlikely to meet such misadventure in the future. Yet the withdrawal of approximately one third of our normal medical strength has brought to light certain aspects of the Procurement and Assignment Service that seem worthy of comment.

The usual age grouping used by the Procurement and Assignment Service divides doctors into four classes: those thirty-eight years old or under — young enough to be amenable to Selective Service persuasiveness; those thirty-nine to forty-four years old — of military interest but beyond the reach of Selective Service; those forty-five to sixty-four — of comparatively little military interest but of great use to civilian needs; and those sixty-five years old or over.

Of our 2900 officers, approximately two thirds are in the first group. They were easily procured because, if not in military service as medical students, they were reported to Selective Service when they did not apply for commissions shortly after they were declared available. The possibility of 1-A classification proved a powerful *vis a tergo*. Therefore, practically all young Massachusetts doctors are now accounted for. Besides those in service are 422 refused commissions by the Surgeons General, 243 declared essential, 75 women, 48 men honorably discharged from active service and 48 foreigners. All medical students in standard schools who are physically eligible for military service are in uniform. Only a few cases still remain to be classified.

The doctors more than thirty-eight years old who are in the Army, Navy and Public Health Service are the ones of whom the Society should feel most proud. They are the true medical volunteers of this war, men who soon learned that Selective Service would put no real pressure on them and who offered their services to their country, often at great personal loss, and solely from a deep sense of patriotism. The Society may well take pride in the fact that all but forty of these officers are of its membership.

The business of relocating physicians continues to be a baffling affair. So far as Massachusetts is concerned but few physicians have been relocated in regions short of medical talent. Your committee has received the impression that many older doctors have preferred, as their war contribution, to work harder than they should rather than to encourage newcomers. They have hoped thereby to hold open positions in their communities for the benefit of local younger men when they return from their military duties. This viewpoint is easily understood and a friendly one. So far, such a policy seems not to have been injurious either to medical or to public health. On the other hand, should replacements be needed in any part of the Commonwealth at any time, there are many young licensed practitioners ineligible for military service who are ready to fill any gap if only they receive encouragement to do so.

The 9-9-9 plan for interns and residents has now in operation long enough so that it moves with less ... than it did when first instituted. Hospitals on the whole less complaining than they were; young doctors educate acceleration appear able to assume clinical responsibilities with surprisingly good effect; residents developed under plan may be not quite so capable or so well trained as were, yet their judicious intermingling with staff of greater experience has made intramural hospital assignments reasonably satisfactory. On the whole the situation in Massachusetts seems to have clarified to a large extent and to have become better adjusted to conditions.

At the October meeting of the Council, the President mented on the tenuous thread by which the Massachusetts Procurement and Assignment Committee of the War Power Commission was related to the Society. Your committee has been thoroughly conscious of this and is grateful to the Council for the privilege of the pleasant relations has been maintained. Your committee also is grateful to Procurement and Assignment committees, which worked so industriously, to hospitals, to medical schools, the Board of Registration in Medicine, to the office of the secretary of the Society and indeed to all who have helped to make its efforts possible.

Henceforward, the work of the Procurement and Assignment Committee promises to be of much less magnitude heretofore and to deal with minor detail rather than broad interests. Problems connected with postwar plans however, are already assuming increasingly large proportions and deserve most careful study.

APPENDIX NO. 5

REPORT OF THE COMMITTEE TO MEET WITH THE MILITARY ADVISORY COMMITTEE OF THE INDUSTRIAL ACCIDENT BOARD

This report is a follow-up in a matter on which a preliminary report was made one year ago.

This committee was appointed at the request of the Industrial Accident Board to recommend procedures for the medical care and surgical care of the injured worker might be improved. It was and still is the opinion of this committee that the surgical staffs of recognized hospitals, by and large, represent the men in any given community most able to cope with surgical conditions.

Our first procedure was to attempt to make these men willing to care for or handle industrial accident cases when they were on duty on ward service. To this end, through co-operation of the chairman of the Industrial Accident Board, it has now been agreed by all the insurance companies handling this type of business that the man rendering emergency treatment to an injured workman shall be paid for such treatment. In defining first-aid treatment it is said that emergency treatment ranges from simple aid to an extensive operation for the relief of a compound fracture. Reasonable charges submitted by any regular physician in this state will be honored. There shall be no change in the relation between the patient and the hospital staff physician as it now exists in the various hospitals of the Commonwealth. The problem of the surgeon on duty caring for an injured employee in the ward without being paid except for the emergency treatment cannot be solved by any method except the passage of an amendment to the law by the General Court providing for the payment for services or a reversal of the ruling previously made by the Supreme Court. It is the opinion of the committee that whereas surgeons on ward service render equally as able to both ward and private patients, it might be well to institute proceedings that would change this rather unfortunate state of affairs.

Payment will not be made for services rendered by interns or residents but for work actually done by surgeons recognized by a hospital, whether or not on duty. This we believe to be a step forward in the better care of the injured workman.

ENDIX NO. 8

STATEMENT OF DR. JACOB FINE

ask your indulgence in making the following statement relative to the report of the Committee on Membership. I all refer to the issues discussed in this report in the order in which they are presented.

The Committee on Membership states that, according to the Board of Registration in Medicine, 309 graduates of foreign medical schools were licensed in Massachusetts from 1933 to 1943. In the 1942 edition of the *American Medical Directory*, the Boston Committee on Medical Emigrés could find more than 165 names of men in this class of licensed physicians who were in actual practice between the years 1933 and 1942. The discrepancy between these figures may therefore be due to the fact that only 165 are in actual practice. The Boston Committee endeavored several times without success to obtain full data from the Board of Registration. In any case it is not clear why this discrepancy would make it difficult for the Committee on Membership to evaluate the remainder of my statement, which deals mainly not with numbers but with the question whether or not the experience of the Society, before or since adoption of the five-year exclusion provision, justifies continuation of this provision.

The Committee on Membership, in reviewing the history of admission of foreign physicians, states, "The general policy operated fairly well until an increasing number of these physicians began to infiltrate Massachusetts." It further states, "No one knew how good an education such people had received." I do not believe that the Committee on Membership means to question the performance of the Board of Registration in Medicine on this point, for the Board certainly knew in every instance what school or schools were attended and the number of hours of instruction received in each course. The report of the Committee on Membership states that according to the chairman of the Committee on Medical Education, it is almost impossible to evaluate the medical education in foreign schools, particularly in Europe. This is to some extent true for those who graduated from continental schools after 1933, but it is certainly not true for those schools before 1933, and the great majority of the medical emigrés graduated before that year.

The report goes on to state, "The by-laws were rewritten in 1939 so as to require that a foreign physician, to be eligible for membership in the Society, must have practiced for a minimum of five years and be recommended by a number of his colleagues who were fellows." I shall quote the next paragraph in the report in full:

The expression "must have practiced for a minimum of five years" was evidently purposely loose; it might mean practice anywhere—indeed including internship as practice—or might be interpreted to mean a minimum of five actual years of practice within the confines of Massachusetts. This was done so that the Committee on Medical Education and Medical Diplomas might interpret the five-year wording as seemed best, admitting easily certain foreign-trained physicians of assured repute but holding back less well-known emigrés from schools about which little was available.

But the very next sentence of the report continues without further explanation as follows, "Finally revised and accepted in May, 1942, the by-laws were clarified." To wit, that the foreign physician shall not be approved for membership unless he had possessed for at least five years a license to practice medicine in the United States or its territories. This the Committee on Membership emphasizes is only a clarification, and not a departure in principle. I submit, with due respect to the committee, that this is not a clarification and that it is indeed a departure in principle, since no foreign physician, however competent or eminent, may now join the Society until five years after he has received

a license to practice in the United States, whereas up to 1932 he could and did join the Society before five years following licensure. It is pertinent at this point to ask whether the experience of the Society between 1939 and 1942, when the five-year exclusion provision was adopted, was such as to require this so-called "clarification." The 1939 amendment, as the report states, was written so as to allow the Committee on Medical Education and Diplomas latitude in judging the admissibility of candidates. What the latter committee had to do was clear enough. Is there any evidence that physicians of dubious qualifications were being certified for membership during the years 1939 to 1942? No such evidence has been offered. If it had been offered, it is not likely that the Committee on Medical Education would have stood its ground in unanimously opposing the five-year exclusion provision.

In the second section of its report the committee notes that the Board of Registration in Medicine requires that the recipient of a license shall become a citizen five years after receipt of the license. The Committee on Membership, however, is of the opinion that, although the recipient of a license is allowed to practice medicine before he becomes a citizen, he should not be admitted to the Society until after he becomes a citizen.

In the third section the Committee on Membership states that the five-year rule will work a hardship on certain foreign-educated physicians, but believes that this is a rare occurrence. Unfortunately this is not so rare an occurrence as the Committee on Membership believes. How can the five-year rule work a hardship? The Committee on Membership like the Boston Committee on Medical Emigrés, is evidently aware that in some towns and cities of this state, the foreign physician is informed that he cannot bring his patients to a hospital because he is not a member of the Massachusetts Medical Society. He must therefore practice medicine for not less than five years before this restriction can be removed. It is not especially helpful to state that American citizens trained abroad have no difficulty in getting hospital appointment, or that many of the best hospitals in this state allow courtesy staff privileges to foreign physicians. Although it is true that for such privileges membership in the Society is not necessary or mandatory, the fact that it is recommended—and no one will question the wisdom of this recommendation—constitutes a basis for exclusion, whenever hospital authorities choose to do so.

In the fourth section the committee states that the five-year provision will not affect foreign physicians who were licensed in 1940 or before, because all of them will have become citizens by 1945, the earliest date possible for removal of the restriction. But I think we shall all agree that the Society is more concerned with whether or not restriction is correct in principle, than with what effect it may have for the moment on a particular group of physicians licensed in any given year. By-laws are not temporary provisions—they embody what are intended to be lasting principles of ethics, standards and procedure.

The committee finally makes the observation that, because foreign physicians did not do substantially better on the Board examination than graduates of unapproved domestic schools, the medical-education standards of European schools are not on a high level and that consequently the five-year exclusion provision is justified. As already stated, the majority of the foreign physicians graduated before 1933. Since the Committee on Membership presumably does not intend to suggest that European medical schools were generally substandard before 1933, the showing of these foreign physicians in the examinations must be explained on a different and quite understandable basis, that is, age and language. We need only to consider whether an average graduate of an American Grade A school, around forty years of age, perhaps practicing in a special field at that, would do better in a licensing examination in a foreign language in a foreign country, a year or so after arriving there, following one or more years out of practice and burdened by a harrowing recent past and a host of immediate difficulties.

50 a hospital, and the appointment and responsibility for the medical personnel, nurses, follow-up workers and clerical help of the clinic. Follow-up of cancer patients until death, and precancerous patients until the precancer is removed, and the maintenance of a uniform record system are required.

The committee shall make arrangements with the hospital in which the clinic meets to furnish examination rooms, instruments, diagnostic x-rays and other essential equipment and supplies.

60 At least three physicians should be present at each clinic session and shall preferably be a surgeon, a radiologist and a pathologist. If available, representatives of the various specialties shall be on call. A nurse is to be in attendance at all clinics.

A clerical worker shall have charge of the clinic files and furnish such reports through the district health officer as may be requested. Uniform record forms will be supplied to the clinics.

Each clinic is to employ a "cancer clinic follow-up worker." This individual will attend to the follow-up and related duties of the clinic. In some of the smaller clinics it may be well, for purposes of economy, to combine the duties of the follow-up worker and the clerical worker. The minimum qualifications for the follow-up worker shall consist of some previous exposure to medical and social problems, as well as some knowledge of the medical and social resources available in the community.

When a problem arises which calls for advice from a medical social worker, unless the cancer-clinic follow-up worker is a trained medical social worker approved by the department, a request for aid should be sent to the local district health officer.

All new appointments of clinic personnel shall be subject to the approval of the department. The department reserves the right to approve on a temporary basis the appointment of personnel who do not meet the minimum qualifications, and to approve other changes in the clinic, during the war emergency.

80 The local cancer clinic committee which petitions for a state-aided clinic shall designate whether it desires to function under Plan A, C or D. These plans have been promulgated in order to give each individual clinic the maximum amount of local autonomy consistent with the Constitution of Massachusetts, the Cancer Act of 1926, as amended by the Act of 1943, and the policies of the Department of Public Health.

90 Plan A. The department will pay for services rendered by the clinic for "such persons as may be in whole or in part unable to support or care for themselves." Each clinic shall determine which individuals are "in whole or in part unable to support or care for themselves." Clinics in hospitals which do not have a prescribed form for determining medical indigency and clinics in those hospitals whose method is not approved by the department shall adopt the department method. This consists of a personal interview with the individual by the admitting office. Due care in selection of the admitting officer is of utmost importance. All individuals coming to the clinic who do not fall into the class of "such persons as may be in whole or in part unable to support or care for themselves" will reimburse the clinic for services. The standard fee shall be \$10, which will include all routine and subsequent follow-up service. This does not include the services of the physicians of the clinic staff which are gratuitous or certain hospital services, such as x-ray examinations, which must be paid by individuals in this class at established hospital rates. Individuals unable to pay \$10 but able to pay some fraction of that amount may do so.

100 Plan C. This plan is somewhat similar to Plan A. All patients seeking consultation service are examined at the clinic and receive advice irrespective of their financial status but the Commonwealth is only billed for "such persons as may be in whole or in part unable to support or care for themselves" and no fee is collected from any individual.

Plan D. Under this plan a clinic may be conducted with other arrangements for payments or for management, or both, provided the arrangement is constitutional, conforms to the legislative mandate, contains local autonomy, is not contrary to public-health practice, and conforms to the American College of Surgeons' plan for making group diagnosis available to all.

120 In order to make the payments equitable for all clinics differing in size and services rendered, the following procedure for payments has been adopted:

Each clinic shall submit monthly a list of services rendered the preceding month. Unit values have been determined for the ordinary services rendered by a cancer clinic. These are termed service units. The service units are totaled for each clinic by the department and then converted into payment units. The payment units of all clinics, with the exception of those which, because of balances due to donations of clubs, individuals, Community Chest, legacies and other sources, do not need current payments, are totaled. The money available for the clinics for a given month is divided by this figure to determine the monetary value of a payment unit. This figure multiplied by the number of payment units for a given clinic minus the money received from patients who pay all or part of the \$10 fee furnishes the amount of clinic payment to be made by the Commonwealth. In this way the Commonwealth pays for none of the services to individuals who can pay for themselves and only for a part of the services of "such persons who may be in whole or in part unable to support or care for themselves," as both physicians

140 and hospitals contribute materially to all groups. After the department has determined the value of the payment unit, an invoice shall be sent to the clinic for signature. On both the monthly report and the invoice, the following certification under penalty of perjury shall be made: "The clinic is billing the Commonwealth only for the services rendered, to the best of our knowledge and belief, to such persons who may be in whole or in part unable to care for themselves."

Itemized accounting of clinic expenditures is required under Plan B, might be required under Plan D, but would not be required under Plans A and C in which the relation between the department and the clinic is that of purchaser and seller of services. The department, however, suggests that if any clinic operating under Plan A or C accumulates a balance due to donations of clubs, individuals, Community Chest, legacies and other sources, such monies be expended in improving the clinic, furthering cancer education or some other form of cancer control.

If major changes in the management of a clinic are contemplated, the approval of the Department of Public Health should be obtained.

The Department of Public Health reserves the right to hire representative make regular inspections of the clinics and make suggestions for improved service. It may cease purchasing service of a clinic which fails in its obligations to the public.

When a clinic ceases to sell service to the Commonwealth, or by a vote of the local group which originally sponsored it, or by vote of the Department of Public Health, it is the responsibility of the department to follow the cancer patients previously seen at clinic, until death. Arrangements must be made either with the clinics, district health units, voluntary agencies or the state cancer-clinic committee, to see that this is done.

APPENDIX NO. 7

REPORT OF THE COMMITTEE ON POSTWAR LOAN FUND

The Committee on Postwar Loan Fund approves in principle the desirability of raising funds from which loans can be made to members of the Massachusetts Medical Society who, having served in the Armed Forces, on discharge from active duty may be in need of immediate financial assistance.

The committee recommends:

That these funds shall be raised by an added annual assessment of \$10 for the duration of the war unless otherwise modified by future action of the Council. This added annual assessment of \$10 is to be levied on all members of the Society not having served in the armed forces during this war.

That payment of the Postwar Loan Fund assessment by members of the Massachusetts Medical Society while in the armed forces be entirely optional.

That payment of the Postwar Loan Fund assessment by members of the Massachusetts Medical Society following discharge from active duty also be entirely optional.

That the amount of loan granted be left to the discretion of the board or committee appointed by the President.

That just enough interest be charged — not to exceed 2 per cent — to cover carrying charges and remind the member obtaining a loan of his obligation.

That no endorsers be required.

That loans shall be limited to a period of twelve months subject to renewal at the discretion of the board or committee appointed.

That only those who were members, in good standing, of the Massachusetts Medical Society on the date they entered the armed forces shall be permitted to borrow from this fund.

That, to inform members of the Society in the armed forces of the availability of this fund, information be printed in the *New England Journal of Medicine*. There shall also appear in a box on the cover of the *Journal* an announcement calling attention of the members to the article on the inside page.

That form letters shall be sent to the members in the armed forces notifying them of the existence of this fund.

That form letters shall be sent out to the other members of the Society with the annual bills for dues bringing to their attention the existence of this fund and its purpose.

That the fund shall be administered from the headquarters of the Massachusetts Medical Society.

That the president of the Massachusetts Medical Society appoint a committee or board of five members, to include the treasurer and the secretary of the Society and the present chairman of the Committee on Postwar Loan Fund, to administer this fund.

GEORGE LEONARD SCHATZ, Chairman

APPENDIX NO. 8

STATEMENT OF DR. JACOB FINE

ask your indulgence in making the following statement relative to the report of the Committee on Membership. I will refer to the issues discussed in this report in the order in which they are presented.

The Committee on Membership states that, according to the Board of Registration in Medicine, 309 graduates of foreign medical schools were licensed in Massachusetts from 1913 to 1943. In the 1942 edition of the *American Medical Directory*, the Boston Committee on Medical Emigrés could find more than 165 names of men in this class of licensed physicians who were in actual practice between the years 1913 and 1942. The discrepancy between these figures may well be due to the fact that only 165 are in actual practice. The Boston Committee endeavored several times without success to obtain full data from the Board of Registration. In any case it is not clear why this discrepancy would make it difficult for the Committee on Membership to evaluate the remainder of my statement, which deals mainly not with numbers but with the question whether the experience of the Society, before or since adoption of the five-year exclusion provision, justifies continuation of this provision.

The Committee on Membership, in reviewing the history of admission of foreign physicians, states, "The general policy operated fairly well until an increasing number of these physicians began to infiltrate Massachusetts." It further states, "No one knew how good an education such people had received." I do not believe that the Committee on Membership means to question the performance of the Board of Registration in Medicine on this point, for the Board certainly knew in every instance what school or schools were attended and the number of hours of instruction received at each course. The report of the Committee on Membership states that according to the chairman of the Committee on Medical Education, it is almost impossible to evaluate the medical education in foreign schools, particularly in Europe. This is to some extent true for those who graduated from continental schools after 1933, but it is certainly not true for those schools before 1933, and the great majority of the medical emigrés graduated before that year.

The report goes on to state, "The by-laws were rewritten in 1939 so as to require that a foreign physician, to be eligible for membership in the Society, must have practiced for a minimum of five years and be recommended by a number of his colleagues who were fellows." I shall quote the next paragraph in the report in full:

The expression "must have practiced for a minimum of five years" was evidently purposely loose; it might mean practice anywhere—indeed including internship as practice—or might be interpreted to mean a minimum of five actual years of practice within the confines of Massachusetts. This was done so that the Committee on Medical Education and Medical Diplomas might interpret the five-year wording as seemed best, admitting easily certain foreign-trained physicians of assured reputability but holding back less well-known emigrés from schools about which little was available.

But the very next sentence of the report continues without further explanation as follows, "Finally revised and accepted in May, 1942, the by-laws were clarified." To wit, that the foreign physician shall not be approved for membership unless he had possessed for at least five years a license to practice medicine in the United States or its territories. This the Committee on Membership emphasizes is only a clarification, and not a departure in principle. I submit, with due respect to the committee, that this is not a clarification and that it is indeed a departure in principle, since no foreign physician, however competent or eminent, may now join the Society until five years after he has received

a license to practice in the United States, whereas up to 1942 he could and did join the Society before five years following licensure. It is pertinent at this point to ask whether the experience of the Society between 1939 and 1942, when the five-year exclusion provision was adopted, was such as to require this so-called "clarification." The 1939 amendment, as the report states, was written so as to allow the Committee on Medical Education and Diplomas latitude in judging the admissibility of candidates. What the latter committee had to do was clear enough. Is there any evidence that physicians of dubious qualifications were being certified for membership during the years 1939 to 1942? No such evidence has been offered. If it had been offered, it is not likely that the Committee on Medical Education would have stood its ground in unanimously opposing the five-year exclusion provision.

In the second section of its report the committee notes that the Board of Registration in Medicine requires that the recipient of a license shall become a citizen five years after receipt of the license. The Committee on Membership, however, is of the opinion that, although the recipient of a license is allowed to practice medicine before he becomes a citizen, he should not be admitted to the Society until after he becomes a citizen.

In the third section the Committee on Membership states that the five-year rule will work a hardship on certain foreign-educated physicians, but believes that this is a rare occurrence. Unfortunately this is not so rare an occurrence as the Committee on Membership believes. How can the five-year rule work a hardship? The Committee on Membership like the Boston Committee on Medical Emigrés, is evidently aware that in some towns and cities of this state, the foreign physician is informed that he cannot bring his patients to a hospital because he is not a member of the Massachusetts Medical Society. He must therefore practice medicine for not less than five years before this restriction can be removed. It is not especially helpful to state that American citizens trained abroad have no difficulty in getting hospital appointment, or that many of the best hospitals in this state allow courtesy staff privileges to foreign physicians. Although it is true that for such privileges membership in the Society is not necessary or mandatory, the fact that it is recommended—and no one will question the wisdom of this recommendation—constitutes a basis for exclusion, whenever hospital authorities choose to do so.

In the fourth section the committee states that the five-year provision will not affect foreign physicians who were licensed in 1940 or before, because all of them will have become citizens by 1945, the earliest date possible for removal of the restriction. But I think we shall all agree that the Society is more concerned with whether or not restriction is correct in principle, than with what effect it may have for the moment on a particular group of physicians licensed in any given year. By-laws are not temporary provisions—they embody what are intended to be lasting principles of ethics, standards and procedure.

The committee finally makes the observation that, because foreign physicians did not do substantially better on the Board examination than graduates of unapproved domestic schools, the medical-education standards of European schools are not on a high level and that consequently the five-year exclusion provision is justified. As already stated, the majority of the foreign physicians graduated before 1933. Since the Committee on Membership presumably does not intend to suggest that European medical schools were generally substandard before 1933, the showing of these foreign physicians in the examinations must be explained on a different and quite understandable basis, that is, age and language. We need only to consider whether an average graduate of an American Grade A school, around forty years of age, perhaps practicing in a special field at that, would do better in a licensing examination in a foreign language in a foreign country, a year or so after arriving there, following one or more years out of practice and burdened by a harrowing recent past and a host of immediate difficulties.

50 a hospital, and the appointment and responsibility for the medical personnel, nurses, follow-up workers and clerical help of the clinic. Follow-up of cancer patients until death, and precancerous patients until the precancer is removed, and the maintenance of a uniform record system are required.

The committee shall make arrangements with the hospital in which the clinic meets to furnish examination rooms, instruments, diagnostic x-rays and other essential equipment and supplies.

At least three physicians should be present at each clinic session and shall preferably be a surgeon, a radiologist and a pathologist. If available, representatives of the various specialties shall be on call.

A nurse is to be in attendance at all clinics.

A clerical worker shall have charge of the clinic files and furnish such reports through the district health officer as may be requested. Uniform record forms will be supplied to the clinics.

Each clinic is to employ a "cancer clinic follow-up worker." This individual will attend to the follow-up and related duties of the clinic. In some of the smaller clinics it may be well, for purposes of economy, to combine the duties of the follow-up worker and the clerical worker. The minimum qualifications for the follow-up worker shall consist of some previous exposure to medical and social problems, as well as some knowledge of the medical and social resources available in the community.

When a problem arises which calls for advice from a medical social worker, unless the cancer-clinic follow-up worker is a trained medical social worker approved by the department, a request for aid should be sent to the local district health officer.

All new appointments of clinic personnel shall be subject to the approval of the department. The department reserves the right to approve on a temporary basis the appointment of personnel who do not meet the minimum qualifications, and to approve other changes in the clinic, during the war emergency.

The local cancer clinic committee which petitions for a state-aided clinic shall designate whether it desires to function under Plan A, C or D. These plans have been promulgated in order to give each individual clinic the maximum amount of local autonomy consistent with the Constitution of Massachusetts, the Cancer Act of 1926, as amended by the Act of 1943, and the policies of the Department of Public Health.

Plan A. The department will pay for services rendered by the clinic for "such persons as may be in whole or in part unable to support or care for themselves." Each clinic shall determine which individuals are "in whole or in part unable to support or care for themselves." Clinics in hospitals which do not have a prescribed form for determining medical indigency and clinics in those hospitals whose method is not approved by the department shall adopt the department method. This consists of a personal interview with the individual by the admitting office. Due care in selection of the admitting officer is of utmost importance. All individuals coming to the clinic who do not fall into the class of "such persons as may be in whole or in part unable to support or care for themselves" will reimburse the clinic for services. The standard fee shall be \$10, which will include all routine and subsequent follow-up service. This does not include the services of the physicians of the clinic staff which are gratuitous or certain hospital services, such as x-ray examinations, which must be paid by individuals in this class at established hospital rates. Individuals unable to pay \$10 but able to pay some fraction of that amount may do so.

Plan C. This plan is somewhat similar to Plan A. All patients seeking consultation service are examined at the clinic and receive advice irrespective of their financial status but the Commonwealth is only billed for "such persons as may be in whole or in part unable to support or care for themselves" and no fee is collected from any individual.

Plan D. Under this plan a clinic may be conducted with other arrangements for payments or for management, or both, provided the arrangement is constitutional, conforms to the legislative mandate, contains local autonomy, is not contrary to public-health practice, and conforms to the American College of Surgeons' plan for making group diagnosis available to all.

In order to make the payments equitable for all clinics differing in size and services rendered, the following procedure for payments has been adopted:

Each clinic shall submit monthly a list of services rendered the preceding month. Unit values have been determined for the ordinary services rendered by a cancer clinic. These are termed service units. The service units are totaled for each clinic by the department and then converted into payment units. The payment units of all clinics, with the exception of those which, because of balances due to donations of clubs, individuals, Community Chest, legacies and other sources, do not need current payments, are totaled. The money available for the clinics for a given month is divided by this figure to determine the monetary value of a payment unit. This figure multiplied by the number of payment units for a given clinic minus the money received from patients who pay all or part of the \$10 fee furnishes the amount of clinic payment to be made by the Commonwealth. In this way the Commonwealth pays for none of the services to individuals who can pay for themselves and only for a part of the services of "such persons who may be in whole or in part unable to support or care for themselves," as both physicians and hospitals contribute materially to all groups.

After the department has determined the value of the payment unit, an invoice shall be sent to the clinic for signature. On both the monthly report and the invoice, the following certification under penalty of perjury shall be made: "The clinic is billing the Commonwealth only for the services rendered, to the best of our knowledge and belief, to such persons who may be in whole or in part unable to care for themselves."

Itemized accounting of clinic expenditures is required under Plan B, might be required under Plan D, but would not be required under Plans A and C in which the relation between the department and the clinic is that of purchaser and seller of services. The department, however, suggests that if any clinic operating under Plan A or C accumulates a balance due to donations of clubs, individuals, Community Chest, legacies and other sources, such monies be expended in improving the clinic, furthering cancer education or some other form of cancer control.

If major changes in the management of a clinic are contemplated, the approval of the Department of Public Health should be obtained.

The Department of Public Health reserves the right to employ representative make regular inspections of the clinics and make suggestions for improved service. It may cease purchasing service to a clinic which fails in its obligations to the public.

When a clinic ceases to sell service to the Commonwealth, by a vote of the local group which originally sponsored it, or by vote of the Department of Public Health, it is the responsibility of the department to follow the cancer patients previously seen in the clinic, until death. Arrangements must be made either with clinics, district health units, voluntary agencies or the cancer-clinic committee, to see that this is done.

APPENDIX NO. 7

REPORT OF THE COMMITTEE ON POSTWAR LOAN FUND

The Committee on Postwar Loan Fund approves in principle the desirability of raising funds from which loans can be made to members of the Massachusetts Medical Society who, having served in the Armed Forces, on discharge from active duty may be in need of immediate financial assistance.

The committee recommends:

That these funds shall be raised by an added annual assessment of \$10 for the duration of the war unless otherwise modified by future action of the Council. This added annual assessment of \$10 is to be levied on all members of the Society not having served in the armed forces during this war.

That payment of the Postwar Loan Fund assessment by members of the Massachusetts Medical Society while in the armed forces be entirely optional.

That payment of the Postwar Loan Fund assessment by members of the Massachusetts Medical Society following discharge from active duty also be entirely optional.

That the amount of loan granted be left to the discretion of the board or committee appointed by the President.

That just enough interest be charged — not to exceed 2 per cent — to cover carrying charges and remind the member obtaining a loan of his obligation.

That no endorsers be required.

That loans shall be limited to a period of twelve months subject to renewal at the discretion of the board or committee appointed.

That only those who were members, in good standing of the Massachusetts Medical Society on the date they entered the armed forces shall be permitted to borrow from this fund.

That, to inform members of the Society in the armed forces of the availability of this fund, information be printed in the *New England Journal of Medicine*. There shall also appear in a box on the cover of the *Journal* an announcement calling attention of the members to the article on the inside page.

That form letters shall be sent to the members in the armed forces notifying them of the existence of this fund.

That form letters shall be sent out to the other members of the Society with the annual bills for dues bringing to their attention the existence of this fund and its purpose.

That the fund shall be administered from the headquarters of the Massachusetts Medical Society.

That the president of the Massachusetts Medical Society appoint a committee or board of five members, to include the treasurer and the secretary of the Society and the present chairman of the Committee on Postwar Loan Fund, to administer this fund.

GEORGE LEONARD SCHAFF, Chairman

there were moist basal rales and respiratory rales throughout the lungs. Her condition became progressively worse, and she died on the sixth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. J. H. MEANS: If we say that this woman obviously died of Bright's disease, no one can refute that we have to do better than that because there is more than one type of Bright's disease. I think that we may assume that she died of azotemia or uremia resulting from renal failure, in turn resulting in some kind of renal nephropathy with infection toward the end, and left ventricular failure, due either to her disease or perhaps to overtreatment. So, she apparently had mild diabetes.

The differential diagnosis as I see it is really one of what kind of kidney lesion she had, and what kind of infection. Perhaps we should take up the latter first. I can see no evidence of infection anywhere except in the urinary tract. The lung picture does not sound to me like an infectious process. She had pus in the urine, and therefore I think that she probably had a urinary-tract infection and I will let it go at that for the moment.

The type of kidney lesion is an interesting subject for differential diagnosis. One might ask, Did she die of one of the more usual forms of chronic kidney lesion to which we may give the clinical name of Bright's disease, or did she have a rarer type of nephropathy? We have to go into all that to suppose to satisfy the requirements of these exercises, but I think from the practical point of view this is of little importance, as both Dr. Thorn and Dr. Cutler have emphasized that the physiologic abnormalities are much more important to identify and treat than is the precise nature of the anatomic lesion.

This patient had acidosis and she was hyperglycemic. She may have had a high threshold for sugar. She had a low blood sodium. These were the things that they had to treat. They gave fluid because of the dehydration, and sodium lactate because of the acidosis. I do not know why they gave 5 per cent glucose in water, because the sodium was low. The sodium racemic lactate was also given because of the acidosis. I do not know how much of the substance 40 cc. represents.

Was this chronic glomerulonephritis? It could have been, but I have a notion that it was not, and I am not going to give any reason. It could, of course, have been a vascular nephritis with malignant hypertension, and I suppose it could have been a chronic pyelonephritis. In their monograph about pyelonephritis Weiss and Parker¹ mention that it is often associated with severe hypertension, that retinopathy may occur, as in this case, that there is often a terminal infection with ventricular failure, as in this case, and that the hypertension may progress after the renal disease is in a healed stage.

This patient may not have started off with pyelonephritis, but may have had some other chronic kidney disease, picking up an acute pyelitis not long before death. I do not know how anyone can tell whether it was pyelonephritis from the start or something else to which pyelonephritis was later added. I rather favor the addition of an acute pyelonephritis toward the end because the infection seems to have been recent. Although the diabetes had been mild for a long time, it became worse toward the end. Its aggravation may have been the result of infection, and the change may have been the last straw that broke the camel's back and precipitated failure in kidneys that were chronically diseased.

I have mentioned four possibilities, and I think that we should now turn our attention to the more specialized nephritides. I do not know much about it but the fact that she had diabetes makes me think of the special kind of lesion that one gets with diabetes that is called "intercapillary glomerulosclerosis." I looked up Newburger and Peters² on that subject to find out the clinical manifestations that one can expect, and found that they described this disease as running a chronic course; many of the features of malignant hypertension may be present, including hypertensive retinopathy, perhaps albuminuria and marked evidence of renal failure toward the end. They also say, and it fits this case perfectly, that the diabetes is often mild, usually requiring little or no insulin for control except when an infection supervenes. In none of their cases did the diabetes tend to influence the progress of the disease. All I can say is that this case in most of its aspects fits that possibility fairly well. That does not mean, however, that it is the correct diagnosis.

I did in passing think of nephropathy due to hyperparathyroidism, but this patient did not have hyperparathyroidism according to the evidence, so we can throw that out. I do not see how it could have been nephropathy due to lymphoma, and I shall also throw that out.

We come finally to the lobular mass in the right flank. If I knew that the man who examined the patient really knew that he was feeling a mass it would help me a great deal. I have to approach the problem on the basis that he did feel one. Therefore, with chronic nephropathy and renal failure, one is bound to consider the possibility that this was a case of congenital polycystic kidneys with renal failure. I believe, barring the diabetes, that that diagnosis would cover everything in this record. Polycystic kidneys usually make themselves evident early in childhood, as I understand it. If the disease does not turn up then, it is apt to appear later in life, as in this case. Weiss and Parker make the intriguing statement that polycystic kidneys, hypertension and renal tuberculosis are often complicated by pyelonephritis. Perhaps the sequence of events here was that the patient had

CASE 30301

PRESENTATION OF CASE

A sixty-three-year-old housewife entered the hospital because of tiredness, exhaustion and weakness.

The patient was apparently well until eight years prior to entry, when she was told that she had high blood pressure. She had had frequency of urination and "trouble with her eyes" but otherwise remained asymptomatic until eight months before admission, when, following the death of her sister, she felt run down and exhausted. Her appetite became poor. About one week before entry she was seen by her physician, who found retinal exudate and hemorrhages, with a slightly enlarged heart and a blood pressure of 220 systolic, 120 diastolic. Urinalysis revealed a specific gravity of 1.018 and a +++ test for albumin with many pus cells and bacteria in the sediment. She was advised to take 1 gm. of sulfadiazine daily, but because of anorexia, nausea, vomiting and diarrhea, she took only 0.5 gm. daily. She was unable to take anything by mouth. She developed slight fever on the day before entry. She had had no headaches, shortness of breath, edema, orthopnea, chest pain, palpitation or chills.

Eight years before admission she had an ulcer on the right shin that healed very slowly. At that time she was found to have mild diabetes, which was controlled by regulation of diet. Urine tests performed by the patient three times daily had remained pale green. She had recently developed polydipsia. She had lost 15 pounds in weight in one year.

One sister had hypertension and died of cerebral hemorrhage. One brother died of "shock." Her mother died at eighty years of age of cerebral hemorrhage, and her father at sixty-seven of acute Bright's disease. There was no family history of diabetes. She had one son who was living and well.

Physical examination showed a well-developed, dehydrated, weak, apathetic woman showing evidence of recent weight loss. The oral mucosa was dry. The retinas showed marked arterial narrowing, tortuosity and arteriovenous nicking; on the right side several hemorrhages and an exudate were seen. The nasal half of the left optic disk was indistinct. The left border of cardiac dullness was just to the

right of the midclavicular line. The sounds, of good quality and regular. The aortic sound was greater than the pulmonic. The lungs were clear. The abdomen was normal. Arterial pulsations were poor in the lower extremities, but no color or temperature changes were noted.

The blood pressure was 156 to 140 systolic, 100 to 90 diastolic. The temperature was 102°F., the pulse 120, and the respirations 25.

Examination of the blood showed a white count of 15,200, with 84 per cent neutrophils. Hemoglobin was 10.1 gm. per 100 cc. The urine was alkaline, with a specific gravity of 1.010. There was a ++ test for albumin, but no sugar, diacetic acid or acetone. The sediment contained 10 red cells and 100 white cells, with rare clumps, per high power field. A urine culture gave no growth. The fasting blood sugar was 286 mg. per 100 cc., and the nonprotein nitrogen 135 mg. The carbon dioxide combining power was 10.3 millimol. per liter, and the sodium 129 milliequiv.

The patient was given 1500 cc. of 2.5 per cent glucose in physiologic saline solution intravenously followed by 1000 cc. of the same solution to which an ampule of sodium lactate had been added. Two grams of triple bromides was given immediately and daily for two days thereafter. Following the two intravenous solutions she still seemed dehydrated, an uremic odor was noted in the breath; the vomiting apparently subsided. On the second and third hospital days she received daily 1000 cc. of 5 per cent glucose in water to which 40 cc. of sodium race lactate had been added, followed by 1500 cc. of 5 per cent of dextrose in 0.3 normal saline solution as well as thiamine chloride, ascorbic acid and riboflavin intravenously.

On the second hospital day the nonprotein nitrogen was 165 mg. per 100 cc., and the sugar 278 mg. The urine output on the third hospital day was 1000 cc. on an intake of 3000 cc. Urinalysis remained essentially as before. On the afternoon of the third hospital day, following the administration of an intravenous fluid, she began to cough, complained of pressure in the chest and became drowsy and extremely apprehensive. She vomited with every intake by mouth, and her color became poor. The lungs showed many basal rales. She was placed in an oxygen tent. Twelve hours later she was still cyanotic but not dyspneic; there were rhonchi in the trachea and a few rales and squeaks in the lungs. She was given 8 mg. of Cedilanid intravenously, followed by 11 mg. (1/6 gr.) of morphine sulfate, followed by 0.1 gm. of digitalis daily. In the next few hours she improved temporarily and the vomiting subsided. The abdomen became quite distended, and the examiner felt a questionable lobulated mass in the right flank. There was no peripheral edema. Later that day she again became drowsy and developed uremic frost in the nose; the respirations became shallow and rapid. The heart sounds were w

*On leave of absence.

there were moist basal rales and respiratory rales throughout the lungs. Her condition became progressively worse, and she died on the sixth fatal day.

DIFFERENTIAL DIAGNOSIS

R. J. H. MEANS: If we say that this woman obviously died of Bright's disease, no one can refute that we have to do better than that because there is more than one type of Bright's disease. I think we may assume that she died of azotemia or uremia resulting from renal failure, in turn resulting in some kind of renal nephropathy with infection toward the end, and left ventricular failure, due either to her disease or perhaps to overtreatment. So she apparently had mild diabetes.

The differential diagnosis as I see it is really one of what kind of kidney lesion she had, and what kind of infection. Perhaps we should take up the latter first. I can see no evidence of infection anywhere except in the urinary tract. The lung picture does not sound to me like an infectious process. She had pus in the urine, and therefore I think that she probably had a urinary-tract infection and I will let it go at that for the moment.

The type of kidney lesion is an interesting subject for differential diagnosis. One might ask, Did she die of one of the more usual forms of chronic kidney lesion to which we may give the clinical name of Bright's disease, or did she have a rarer type of nephropathy? We have to go into all that to suppose to satisfy the requirements of these exercises, but I think from the practical point of view it is of little importance, as both Dr. Thorn and Dr. Cutler have emphasized that the physiologic abnormalities are much more important to identify and treat than is the precise nature of the anatomic lesion.

This patient had acidosis and she was hyperglycemic. She may have had a high threshold for sugar. She had a low blood sodium. These were the things that they had to treat. They gave fluid because of the dehydration, and sodium lactate because of the acidosis. I do not know why they gave 5 per cent glucose in water, because the sodium was low. The sodium racemic lactate was also given because of the acidosis. I do not know how much of the substance 40 cc. represents.

Was this chronic glomerulonephritis? It could have been, but I have a notion that it was not, and I am not going to give any reason. It could, of course, have been a vascular nephritis with malignant hypertension, and I suppose it could have been a chronic pyelonephritis. In their monograph about pyelonephritis Weiss and Parker¹ mention that it is often associated with severe hypertension, that retinopathy may occur, as in this case, that there is often a terminal infection with ventricular failure, as in this case, and that the hypertension may progress after the renal disease is in a healed stage.

This patient may not have started off with pyelonephritis, but may have had some other chronic kidney disease, picking up an acute pyelitis not long before death. I do not know how anyone can tell whether it was pyelonephritis from the start or something else to which pyelonephritis was later added. I rather favor the addition of an acute pyelonephritis toward the end because the infection seems to have been recent. Although the diabetes had been mild for a long time, it became worse toward the end. Its aggravation may have been the result of infection, and the change may have been the last straw that broke the camel's back and precipitated failure in kidneys that were chronically diseased.

I have mentioned four possibilities, and I think that we should now turn our attention to the more specialized nephritides. I do not know much about it but the fact that she had diabetes makes me think of the special kind of lesion that one gets with diabetes that is called "intercapillary glomerulosclerosis." I looked up Newburger and Peters² on that subject to find out the clinical manifestations that one can expect, and found that they described this disease as running a chronic course; many of the features of malignant hypertension may be present, including hypertensive retinopathy, perhaps albuminuria and marked evidence of renal failure toward the end. They also say, and it fits this case perfectly, that the diabetes is often mild, usually requiring little or no insulin for control except when an infection supervenes. In none of their cases did the diabetes tend to influence the progress of the disease. All I can say is that this case in most of its aspects fits that possibility fairly well. That does not mean, however, that it is the correct diagnosis.

I did in passing think of nephropathy due to hyperparathyroidism, but this patient did not have hyperparathyroidism according to the evidence, so we can throw that out. I do not see how it could have been nephropathy due to lymphoma, and I shall also throw that out.

We come finally to the lobular mass in the right flank. If I knew that the man who examined the patient really knew that he was feeling a mass it would help me a great deal. I have to approach the problem on the basis that he did feel one. Therefore, with chronic nephropathy and renal failure, one is bound to consider the possibility that this was a case of congenital polycystic kidneys with renal failure. I believe, barring the diabetes, that that diagnosis would cover everything in this record. Polycystic kidneys usually make themselves evident early in childhood, as I understand it. If the disease does not turn up then, it is apt to appear later in life, as in this case. Weiss and Parker make the intriguing statement that polycystic kidneys, hypertension and renal tuberculosis are often complicated by pyelonephritis. Perhaps the sequence of events here was that the patient had

congenital polycystic kidneys that functioned well until eight years before her terminal illness; the kidneys then became incompetent and finally picked up an infection, the diabetes got worse, and she died.

All I can do is make these two suggestions, which I put on a par, because I do not know whether or not a mass was really felt. If it was, I would favor polycystic kidneys. If there was no mass, I would incline toward intercapillary glomerulosclerosis. It may have been neither of these — just a more ordinary kind of chronic nephritis.

DR. ALLAN M. BUTLER: Dr. Means asked about the amount of racemic sodium lactate in 40 cc. That

Congenital polycystic kidneys and liver.
Acute pyelonephritis.
Bacteremia (colon bacillus).
Pulmonary edema.
Bronchopneumonia.
Cardiac hypertrophy, hypertensive type.
Coronary sclerosis, severe.
Myocardial fibrosis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy on this patient showed a pair of polycystic kidneys, with

FIGURE 1. Photograph of Kidneys.

is difficult to answer because it does not give the concentration. The commercial ampules, however, contain 40 cc. of 1 molar sodium lactate, which has the same quantity of sodium that is contained in approximately 250 cc. of physiologic saline solution.

CLINICAL DIAGNOSES

Essential hypertension.
Pyelonephritis.
Hypertensive coronary heart disease.
Mild diabetes.
Congestive heart failure, terminal.

DR. MEANS'S DIAGNOSES

Congenital polycystic kidneys or intercapillary glomerulosclerosis.
Acute pyelonephritis, recent.
Uremia.
Diabetes mellitus.
Left ventricular cardiac failure.

together weighed 700 gm. (Fig. 1). A moderate amount of renal parenchyma was still present, but a large portion of it certainly was replaced by congenital cysts. In addition there was an acute pyelonephritis, characterized by large foci of polymorphonuclear and eosinophilic infiltration. A post-mortem blood culture yielded colon bacilli, which probably arose from the pyelonephritis. For acute infection were present in other organs including the liver, secondary to the terminal bacteremia.

There were also congenital cysts in the liver. It occurs in about 20 per cent of the cases of polycystic kidneys. In addition to the large cysts there were grayish-white, moderately firm areas, 2 to 3 in diameter, throughout the liver that in gross dissection resembled metastatic carcinoma. These proved microscopically to be foci of aberrant bile ducts, a condition that may be associated with congenital cystic disease of the liver. Some of these ducts were dilated and filled with fluid and polymorphonuclear leukocytes. Others were suggestive

use cholangioma, but there was no bile in any of these small nodules and they are best interpreted as part of the congenital process within the liver. The heart was enlarged, weighing 500 gm., and showed large areas of scarring throughout, due to severe coronary sclerosis. There was also severe pulmonary edema and early bronchopneumonia. We found no anatomic evidence of diabetes; the islets of Langerhans were normal.

CASE 30302

PRESENTATION OF CASE

A forty-seven-year-old housewife entered the hospital for study.

The patient had been in apparent good health, except for mild indigestion and intolerance for fatty and fried foods of many years' duration, until five or six months before entry when she noted a feeling of bloatedness, considerable eructation and passage of gas by rectum. She had no nausea or vomiting but voluntarily limited her intake of food. About five months before admission she had a feeling of constricting pressure in the right upper quadrant when wearing a girdle. About the same time she noted a hard mass in the right upper quadrant. The mass gradually became larger, and one week before entry she consulted a physician, who advised hospitalization.

Four days prior to entry the patient had an attack of severe pain over the lower part of the mass, which was tender. She became nauseated and vomited, the vomitus consisting of bile-stained material without blood. She had been constipated. The pain persisted and she was brought into the Emergency Ward. She had lost about 20 pounds since the onset of her illness.

Physical examination showed a well-developed, slightly undernourished woman in no discomfort. The heart and lungs were normal. There was a firm, tender, irregular mass in the midepigastrium extending to the right side of the abdomen and in the midline to 2 cm. below the umbilicus. A questionable liver edge was palpated in the right flank and seemed to be attached to the mass. The mass moved slightly with respiration. Its lower edge was more or less freely movable, the upper part was firmly attached and immobile. The mass was dull to flat on percussion. Peristalsis was normal. No other masses or tenderness was elicited. Vaginal and rectal examinations were negative except for a feeling of fullness in the cul-de-sac.

The blood pressure was 116 systolic, 70 diastolic. The temperature was 98.6°F., the pulse 90, and the respirations 20.

The red-cell count was 3,780,000, with 10.5 gm. of hemoglobin. The white-cell count was 5700, with 66 per cent neutrophils. The urine was normal. A blood Hinton test was negative. Three stool examinations were guaiac negative, but one examination gave a +++ test. The blood sugar was 113.5 mg. per 100 cc. The nonprotein nitrogen was 19 mg. per 100 cc., and the chloride 101 milliequiv. per liter. A van den Bergh test was normal. The prothrombin time was 27 seconds (normal, 18 to 20 seconds). The serum protein was 7.01 gm. per 100 cc., with 4.27 gm. of albumin and 2.74 gm. of globulin. A cephalin flocculation test was negative in twenty-four hours, and + in forty-eight hours.

An x-ray examination of the chest was negative. A Graham test failed to visualize the gall bladder. No stones were seen. An intravenous pyelogram showed normal kidneys, pelves, ureters and bladder. A soft-tissue mass was present in the midline at the level of the second lumbar vertebra that caused an extrinsic defect on the stomach distal to the angulus. The psoas shadows were distinct. Barium examination of the colon showed it to fill readily without obstruction; the examination was unsatisfactory, but the above described mass seemed to be extrinsic to the colon. The cecum was freely movable and nontender. The mucosal pattern was normal.

A gastrointestinal series showed a normal esophagus. The stomach was deformed by pressure from an extrinsic mass beginning at the angulus on the greater curvature and filling the space between the angulus and the descending loop of the duodenum (Fig. 1). The mucosa over this large, smooth, round mass showed no ulceration. As soon as the barium entered the second portion of the duodenum, a large clump of barium was seen in the region of the mass that showed no mucosal pattern. The barium, however, did pass into the jejunum, and in the lateral projection this seemed to lie posteriorly, widening the duodenal curve. Films taken three hours after the meal showed a large mass of barium still in the region of the mass (Fig. 2). A 1-by-2-cm. area that was free of barium was present above the mass. This area was constant in size, shape and position.

On the third hospital day the patient had a fever of 103°F., with a subsequent fall to normal. She was given 4 mg. of Hykinone intramuscularly every day for three days and then three times a week. The pain was controlled by sedation. On the tenth hospital day the temperature rose to 102°F., and from then on ranged between 102 and 98.6°F. She was given 6 gm. of sulfadiazine daily, several transfusions of whole blood and intravenous fluids.

On the seventeenth hospital day an operation was performed.

DR. JACOB LERMAN: I saw this patient on rounds. Our first impression was that she probably had carcinoma of the transverse colon. After seeing the x-ray films we thought that it had ruptured, had formed a large abscess around the colon and had gradually involved the surrounding organs to explain this peculiar x-ray picture. We also considered hypernephroma, but after seeing the x-ray films we dismissed that diagnosis. Carcinoma of the gall bladder was likewise considered. Most of the service thought that it was carcinoma of the colon.

DR. MOORE: I should have mentioned that the single observation of a positive Graham test without stones does not prove anything one way or another. Since the dye was given by mouth, the pathology in this region could have impaired absorption.

DR. LINTON: Did the mass pulsate?

DR. BENJAMIN CASTLEMAN: No.

CLINICAL DIAGNOSIS

Abdominal tumor (? carcinoma of pancreas).

DR. MOORE'S DIAGNOSIS

Carcinoma of neck or body of pancreas?

Carcinoma of gall bladder, with erosion into duodenum?

ANATOMICAL DIAGNOSIS

Epidermoid carcinoma of gall bladder, with fistulous extension into duodenum and transverse colon.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At operation the surgeon found a huge mass in the right upper quadrant on the

undersurface of the liver and took a small piece. He was also able to scoop out several stones that apparently he got into the center of the bladder. The tissue proved to be an epidermoid carcinoma.

The patient died soon after operation and autopsy showed a mass that measured roughly 20 cm. diameter, which superiorly was firmly attached to the inferior surface of the right lobe of the liver inferiorly had pushed the transverse colon quite a bit. In dissecting the bile ducts we were able to find only the beginning of the cystic duct; the rest of the cystic duct and the gall bladder were replaced by the mass. In the center of it was a large amount of necrotic material, which was secondarily infected. The tumor had perforated into the second portion of the duodenum and also into the transverse colon in two places. The perforation into the duodenum at the time of autopsy measured $\frac{1}{2}$ cm. diameter, and those in the transverse colon measured about 1.5 cm. in diameter. Since the gall bladder had been replaced by the mass and because of the fact that the tumor was an epidermoid carcinoma the diagnosis of carcinoma of the gall bladder becomes fairly certain. There was no involvement of the pancreas.

DR. MOORE: If the tumor had invaded the duodenum on its medial wall it must have involved the pancreas.

DR. CASTLEMAN: It was not exactly medial; anteromedial is a better way of describing it. In the gross examination and in the sections the pancreatic parenchyma was not involved.

DR. ROBBINS: From the x-ray appearance the tumor had to involve the stomach.

DR. CASTLEMAN: Yes; it was adherent to both the stomach and the pancreas but had not invaded either.

The diagnosis of infectious mononucleosis depends on evidence that is rather well defined. Usually the physical examination, blood studies and clinical course suggest the proper diagnosis, which may be confirmed by the sheep-cell agglutination reaction. If infectious mononucleosis is borne in mind in the differential diagnosis of fevers of unknown origin, there should be little difficulty in arriving at the correct diagnosis in most cases. It seems likely that the incidence of this disease, particularly among children and young adults, may be greater than is ordinarily supposed.

The diagnosis of undulant fever is often troublesome. Most cases present few significant physical findings. Often it is difficult to recover the etiologic agent from the blood stream, and positive serologic and skin tests are not necessarily indicative of active infection since both tests may be positive because of previous infection or because of continued use of milk from infected herds.

The authors point out that epidemiologic investigations of cases of undulant fever may be helpful in the diagnosis of this disease. For the most part it is acquired by ingestion of infected dairy products or by contact with animals. It was observed that when reported cases could not be traced either to raw milk or to infected animals, review of the clinical findings sometimes resulted in a change in diagnosis.

Although undulant fever is usually thought of as a rural disease, it may occur among persons living in urban areas in spite of local regulations that forbid the sale of raw milk. In such cases the urban residents usually acquire the disease by the ingestion of raw milk while traveling in regions remote from their homes. Hardy et al.,* in a study of 17 patients living in New York City who had been exposed to infection through the use of raw milk ingested during single out-of-town visits, reported incubation periods varying from one week to four months, the longer one tending to obscure the source of infection. Other urban residents may contract undulant fever as a result of occupational exposure. For example, direct contact with animals or animal carcasses by persons employed in packing

INFECTIOUS MONONUCLEOSIS VERSUS BRUCELLOSIS

An article published in this issue of the *Journal* indicates that the differential diagnosis of infectious mononucleosis and brucellosis may give rise to considerable confusion. The authors discovered 13 cases of infectious mononucleosis by performing the heterophile antibody reaction routinely on a series of one thousand consecutive samples of blood serum submitted by physicians to the State Bacteriological Laboratory for undulant-fever agglutination tests. In 11 of the cases, the physician had not suspected this disease.

houses or rendering plants is often the source of infection. For this reason a careful occupational history may be helpful in the diagnosis of this disease.

Not so many years ago, application of a simple rule of thumb, "Tuberculosis, typhoid fever and sepsis," was fairly adequate in the differential diagnosis of obscure fever. Because of the ever-dwindling incidence of acid-fast and typhoid infections, however, other causes of obscure fever are now becoming relatively more frequent. The State Department of Public Health announces the availability, on request by physicians, of the heterophile antibody reaction. This test should provide additional aid in the diagnosis of unexplained fevers.

PENICILLIN IN EXPERIMENTAL VIRAL AND RICKETTSIAL DISEASES

With few notable exceptions, the new chemotherapeutic agents have been ineffective in the treatment of viral and rickettsial diseases. The exceptions are lymphogranuloma venereum, trachoma and inclusion blenorrhea, which apparently respond favorably to most of the sulfonamide drugs that are now in general use. With the advent of penicillin, it is natural that the field of viral and rickettsial disease should be re-explored for the possibility that infection with some of these nonbacterial agents might prove susceptible to its action. Thus far, no really successful clinical trials in this field have been reported. A few recent studies suggest that penicillin in adequate doses is effective in reducing the mortality from experimental infection of animals with some of these agents.

Heilman and Herrell,^{1, 2} of the Mayo Clinic, have published studies on experimental ornithosis and psittacosis in mice. With both viruses, the authors noted a marked reduction in mortality among the penicillin-treated animals. The virus could always be recovered from the surviving animals long after treatment had been stopped. They suggest that penicillin inhibits the multiplication of virus until immunity has been established. The treatment apparently converted an acute and fatal infection into one that was chronic and relatively benign. The possibility that bacterial infections were present

to account for the differences was not adequately controlled. Furthermore, the results would have been somewhat more convincing had the authors controlled the series with similar sulfonamide-treated animals.

Experiments on the effect of penicillin on murine typhus in the yolk sac of developing chick embryos and in susceptible mice have been carried by Pinkerton and his associates.^{3, 4} These workers conclude that penicillin injected in three doses at intervals of forty-eight hours exerted a striking inhibitory effect on the multiplication of the rickettsias of murine typhus in the yolk sac of the fertilized hen's egg. In these experiments, penicillin was not injected until two or three days after the injection of the rickettsias in order to allow time for the organisms to gain entrance into the cells. Careful study was made of the cells in the yolk sacs of the penicillin-injected eggs, and with the exception of some heavily infected eggs, only a rare isolated organism was seen in such a position that it might have been thought to be intracellular. These observations suggest that the inhibition of rickettsial growth was brought about by penetration of the penicillin into the cells rather than by its direct effect on extracellular organisms in the process of passing from cell to cell.

In mice, Pinkerton and his associates showed that the administration of penicillin in relatively large but nontoxic doses after infection with the rickettsias of murine typhus resulted in a marked reduction in mortality, particularly when the initial infective dose was relatively small, approaching the minimum lethal dosage. They found no evidence of secondary bacterial infection in bacteriologic and histologic studies and thus felt justified in concluding that the greatly increased survival rate in the penicillin-treated mice was caused by the action of penicillin on the rickettsias. The penicillin was usually injected intraperitoneally, and in most of their experiments, there was a daily period of nine hours during which the concentration of the drug was probably not maintained at effective levels. They suggest that, since the human disease is caused by the growth of rickettsias in vascular endothelium, intravenous or intramuscular injection of penicillin should bring the drug into direct contact with the

containing the organisms and that, if sufficiently high concentrations of the drug can be established in the blood stream in the early stages of the disease, it is reasonable to expect a beneficial therapeutic effect. They believe that their results justify a thorough clinical trial of penicillin in human typhus fever. They suggest that treatment in the early stages of the disease is necessary and that the dosage should be increased over that ordinarily used in bacterial infections.

MASSACHUSETTS MEDICAL SOCIETY

EATHS

AUSTIN—James C. Austin, M.D., of Spencer, died July 10. He was in his sixty-ninth year.

Dr. Austin received his degree from Baltimore Medical College in 1896. He had been a practicing physician in Spencer for forty years and was widely known throughout Worcester County. He was chairman of the Board of Health for twenty-five years and served as school physician for many years. He was a past president of the Worcester District Medical Society and a member of the American Medical Association and the Brookfield Medical Society.

His wife, three daughters, a brother and a sister survive.

CUMMINGS—John J. Cummings, M.D., of Worcester, died July 9. He was in his seventy-fifth year.

Dr. Cummings received his degree from Columbia University College of Physicians and Surgeons in 1899. He had been a practicing physician in Worcester and a member of the St. Vincent Hospital staff for more than forty years. For the past fifteen years he had been senior member of the hospital obstetric staff. He was a member of the American Medical Association.

His widow, two sons and two brothers survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

LABORATORY TEST FOR INFECTIOUS MONONUCLEOSIS

The Bacteriological Laboratory at the State House is now prepared to perform tests for heterophile antibody (sheep-cell agglutination) as a means of detecting cases of infectious mononucleosis. Although infectious mononucleosis is not reportable, its infectious character has been recognized for some time.

In a recent study carried on by this department, the results of which appear elsewhere in this issue of the *Journal*, it has been shown that a certain

proportion of blood serums submitted by physicians for the undulant-fever agglutination test gave positive tests for heterophile antibody. Because of the similarity in the clinical manifestations of undulant fever and infectious mononucleosis, one may easily be confused with the other. It is thought that the availability of this test will assist physicians further in diagnosing fevers of undetermined origin.

Physicians requesting this test should submit 5 to 10 cc. of whole blood or serum in a dry, preferably sterile, test tube. The undulant fever outfit issued by this department is adequate for the purpose.

COMMUNICABLE DISEASES IN MASSACHUSETTS FOR JUNE, 1944

RÉSUMÉ

DISEASES	JUNE 1944	JUNE 1943	SEVEN YEAR MEDIAN
Anterior poliomyelitis	1	2	2
Chancroid	4	*	*
Chicken pox	1748	1011	1170
Diphtheria	7	7	7

*Made reportable in December, 1943

†Pfeiffer-bacillus meningitis only other form reportable previous to 1941

COMMENT

Anterior poliomyelitis, fortunately, continued at a low level. The incidence for the past six months is lower than that for the corresponding months in 1943.

Chicken pox showed the usual seasonal decline but was still the highest on record for the month of June.

Diphtheria showed a marked drop after nine months of unusually high prevalence.

Meningococcal meningitis showed a definite decline from March through June, but the prevalence was still above that of 1942. It appears that the peak was reached during the fall and winter and that there will be a gradual decline to interepidemic levels.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Actinomycosis was reported from Medford, 1, total, 1.

Anterior poliomyelitis was reported from Boston, 1, total, 1.

Anthrax was reported from Lowell, 1, total, 1.

Diphtheria was reported from Auburn, 1, Boston, 1, Lawrence, 1; Medford, 2; Needham, 1, Somerville, 1, total, 7.

Dysentery, amebic, was reported from Cushing General Hospital, 1; total, 1.

Dysentery, bacillary, was reported from Worcester, 2, total, 2.

Encephalitis, infectious, was reported from Fall River, 1, Needham, 1, New Bedford, 1; total, 3.

Malaria was reported from Boston, 2, Camp Edwards, 11, Cushing General Hospital, 20, Fall River, 2, Fort Banks, 5, Fort Devens, 13; New Bedford, 1, Salem, 2, Somerville, 1, Woburn, 1, Worcester, 1, total, 59.

Meningitis, meningococcal, was reported from: Arlington, 1; Boston, 8; Braintree, 1; Chelsea, 1; Chicopee, 1; Dennis, 1; Fall River, 1; Fitchburg, 1; Fort Devens, 1; Lawrence, 1; Ludlow, 1; Medway, 1; Nahant, 1; Newton, 1; Oxford, 1; Revere, 1; Springfield, 2; Stoughton, 1; Waltham, 1; Wrentham, 1; total, 28.

Meningitis, pneumococcal, was reported from: Boston, 2; Framingham, 1; total, 3.

Meningitis, other forms, was reported from: Boston, 1; total, 1.

Meningitis, undetermined, was reported from: Boston, 3; Quincy, 2; Winchester, 1; Worcester, 1; Wrentham, 1; total, 8.

Salmonella infections were reported from: Arlington, 1; Boston, 1; Boylston, 1; Cambridge, 1; Everett, 1; Hopedale, 1; Ludlow, 1; Malden, 1; Melrose, 1; Milton, 1; Revere, 1; Salem, 1; Worcester, 1; total, 13.

Septic sore throat was reported from: Arlington, 1; Belmont, 1; Boston, 7; Holyoke, 1; Merrimac, 2; Topsfield, 1; total, 13.

Tetanus was reported from: Dartmouth, 1; Medford, 1; total, 2.

Trachoma was reported from: Beverly, 1; total, 1.

Trichinosis was reported from: Lowell, 2; total, 2.

Typhoid fever was reported from: Boston, 1; Gardner, 1; total, 2.

Undulant fever was reported from: Billerica, 1; Concord, 1; Holyoke, 1; Saugus, 1; Williamstown, 1; total, 5.

MISCELLANY

PULMONARY TUBERCULOSIS ASSOCIATED WITH CONGENITAL HEART DISEASE

When a patient with congenital heart disease acquires tuberculosis it is a serious mishap. The medical adviser must then make the choice between conservative treatment of the tuberculosis and some form of collapse therapy with the attendant risk of burdening the already embarrassed circulatory systems still further. A recent study of a number of cases (Auerbach, O., and Stemmerman, M. G. Development of pulmonary tuberculosis in congenital heart disease. *Am. J. M. Sc.* 207:219-230, 1944) suggests that prompt and active therapy directed at the tuberculosis offers the best chance of preserving the already short life span of these individuals.

* * *

It is commonly accepted that patients suffering from congenital heart disease are prone to develop and later to succumb to pulmonary tuberculosis. Of all patients with congenital heart anomalies it is those with pulmonary stenosis who seem most likely to develop tuberculosis. Whether it occurs more frequently in this group than among a comparable number with normal hearts cannot be stated positively without detailed statistical analyses. Case reports seem to show that tuberculosis is no greater menace in patients with pulmonary stenosis than is their cardiac defect.

It is true, however, that many persons born with this anomaly die before they have relatively much opportunity to develop tuberculosis, many of them being so incapacitated that they are protected from infectious contacts. If predisposition does actually exist it must arise primarily in the faulty oxygen and blood exchange characteristic of these cases.

This study concerns the frequency of congenital heart conditions in a tuberculosis institution, the course of the pulmonary disease and the efficacy and advisability of collapse therapy in the face of the cardiac handicap.

In the course of 1545 necropsy examinations of tuberculous persons, 7 cases of congenital heart disease were discovered, an incidence of 0.4 per cent. This incidence may be higher than in most other tuberculosis institutions owing to the fact that one out of eight beds in this hospital is allotted to peditrics. It is lower than that observed in institutions devoted entirely to the treatment of children.

The diagnosis made from the symptoms and physical examination of 6 additional patients coincided unusually well

with the defects found in the 7 cases that came to autopsies. They exemplify the grouping of cardiac anomalies known as the "tetralogy of Fallot." A picture of this condition is represented by this composite case report: The patient, a white youth in his lower teens. The history records symptoms from birth or shortly thereafter, and the diagnosis of congenital heart disease was made early. At that time he was placed on restricted activity and followed in a hospital out-patient department. He has had no evidence of congestive failure and has led a fairly normal life until the onset of the pulmonary disease. Examinations show a young appearing underdeveloped child not, as a rule, dyspnoeic but with cyanosis and clubbing of the fingers and toes. The heart is enlarged in all dimensions, with a loud, harsh, systolic murmur at the base, usually associated with a systolic thrill. The lung findings are dependent on the pulmonary pathology. Laboratory tests indicate a well-marked polycythemia, and there are tubercle bacilli demonstrable in the sputum. Roentgenography and fluoroscopic examination demonstrate enlargement of both ventricles, frequently more marked in the right, and a prominent pulmonary conus. The venous pressure is within normal limits, and the blood pressure tends to be normal or slightly decreased. In the electrocardiogram is found right-axis deviation with tall P waves, these often being notched. The pulmonary disease has not influenced the findings typical of the combined heart lesions making up the cyanotic group.

The onset of pulmonary disease in these cases was similar to that of patients without congenital heart disease. Some or all of the usual symptoms of tuberculosis were present in all cases. No difficulty was experienced in differentiating the congenital heart disease and pulmonary tuberculosis since the congenital anomaly was diagnosed in 4 cases prior to the onset of the tuberculosis. The disease was moderately or far advanced on admission to the hospital in all but 1 case. The course of the disease and the lesions at autopsy were similar to those observed in patients without the cardiac hazard. The duration of life depended on the extent of the disease on admission and the effectiveness of collapse therapy when that was used. The longest duration in the series of 13 cases was six years, the shortest course was seven months. The average duration of life from the onset of the pulmonary infection to fatal termination was one to two years.

As the lesions and other factors of the pulmonary infection are the same whether or not the patient has congenital heart disease and as the cause of death depends on the pulmonary rather than the cardiac status, it is the lung rather than the heart that should be the local point of therapy. When best rest fails to arrest the progression of the tuberculous infection or cannot accomplish cavity closure it must be supplemented by collapse therapy in spite of the cardiac pathology. When this procedure is adopted late in the course of the disease the possibility of arresting the tuberculosis is slight. The life expectancy of these patients even without the pulmonary complication is short. Nevertheless, therapeutic measures even hazardous ones, seem justifiable if they will prevent the patient from succumbing even more prematurely to tuberculosis.

In the group of cases here reported pneumothorax was instituted in 5 cases. In 1 case only was an effective pneumothorax established. In no case did collapse therapy increase the cardiac symptoms or lead to congestive heart failure.

It is recommended that congenital heart disease should not be considered a contraindication to thoracoplasty at least in order not to deprive these patients of the few years of life expectancy due them, immediate operation may be more advantageous than a preliminary, often disappointing, trial of pneumothorax. — Reprinted from *Tuberculosis Abstracts* (August, 1944).

NOTE

Dr. H. Houston Merritt, associate professor of neurology, Harvard Medical School, and visiting neurologist, Boston City Hospital, has been recently appointed professor of clinical neurology, Columbia University College of Physicians and Surgeons, and chief of the Division of Neuro-psychiatry, Montefiore Hospital, New York City.

BOOK REVIEWS

Mechanism: A physiologic interpretation of causalgia and its related states. By W. K. Livingston, M.D. 8°, cloth, pp., with 26 illustrations and 1 table. New York: The Millan Company, 1943. \$3.75.

Dr. Livingston, a neurosurgeon, has long been interested in the clinical aspects of pain, and this book is a personal record of his investigations of the last few years. He points out what we know about the mechanism of pain and indicates further researches that might be made with profit. The chapters cover the anatomy of pain pathways, the pathology and physiology of pain, the various clinical syndromes and the author's interpretations of the pain phenomenon.

Dr. Livingston draws no final conclusion, since the subject is too complicated, and many questions are still unanswered. He has, nevertheless, certain convictions. One at the concept of specificity in the narrow sense in which it is sometimes used to identify sensory experiences with particular end-organs and nerve fibers has led away from a perspective. He also thinks that it is a mistake to assume that certain pain syndromes must represent an obsession of the psychiatrist's origin. He does not discredit the results of peripheral sympathectomy and novocain injections, but on the ground that their mode of action is obscure. He believes, finally, that chronic irritations of sensory nerves initiate clinical states that are characterized by pain spreading disturbances of function in both somatic and visceral structures. If such disturbances continue, he thinks they are profound, and perhaps unalterable, organic changes may take place in the affected part. The aim of therapy should be to break up this vicious cycle, even if it requires the permanent removal of an anatomic pathway. In many cases, however, simple removal of the trigger point is sufficient to establish relief.

The book in general is a thoughtful summary of a controversial subject and as such is a distinct addition to medical literature.

Coroners Anonymous: The story of laboratory medicine. By William McKee German, M.D. With an introduction by J. de Kruijff. 8°, cloth, 300 pp. New York: Duell, Sloan Pearce, 1941. \$2.75.

The doctors referred to in the title are the pathologists, the author being a distinguished example of that group of scientists. This book is written in an interesting but truly instructive manner for the public and explains the work of the pathologist in a general hospital, as well as including certain details regarding bacteriology and tissue diagnosis from relative specimens, the importance of the autopsy to both the medical profession and the public, and a plea for recognition of the value of the pathologist's position in hospitals. There is an excellent chapter on the coroner's system. It is surprising to learn that in forty-four of the states and in the District of Columbia, sudden, unexplained deaths are investigated by a coroner, and in only six of these states is the coroner required to be a licensed physician. Thus, why people die is a large part of the country is investigated by undertakers, furniture dealers who sell caskets and former politicians with good political connections. Massachusetts, ahead of other states, gave up the coroner system as early as 1877, but it took nearly fifty years for some of her neighbors to follow suit. In spite of state laws, certain cities, particularly New York and San Francisco, have excellently trained medical examiners, who perform the autopsies.

Finally, the author discusses various diseases that, at some time in the history of the country, were important to the pathologist but now are practically extinct, such as chlorosis, scrofula and most types of lead poisoning. There is much of interest to any physician in this well-written book.

Clinical Diagnosis by Laboratory Examinations. By John A. Limer, M.D., Dr.P.H., Sc.D., LL.D., LL.D. 8°, cloth, 59 pp., with 75 illustrations. New York: D. Appleton-Century Company, 1943. \$8.00.

The size of this volume attests to the importance of the laboratory as an integral part of diagnosis. The author offers apologies for those who would circumvent careful clinical study by resorting to numerous laboratory procedures in

the hope of reaching a diagnosis. It has become almost platitudinous to stress the importance of the sequence of bedside study supplemented by any and all necessary laboratory tests. Clinical acumen still has its place.

This book is divided into three portions: the clinical interpretation of laboratory examinations; the practical application of laboratory examinations in clinical diagnosis; and the technic of laboratory examinations. Thus both the laboratory procedures and the tests of visceral functions are discussed, supplemented by numerous tables, which add greatly to the value of the book.

Attention may be called to certain minor omissions and corrections. The frequency with which laboratories report some results in milliequivalents calls for some elucidation. The determination of the ketosteroids in the differentiation of Simmonds's disease and anorexia nervosa is not mentioned. The role of perforated eardrums in yielding faulty basal metabolic readings should be noted. In discussing platelet counting the direct method is entirely omitted, and Dr. Olef's name is misspelled.

On the whole, this is a book that richly deserves a handy place not on the shelf but on the laboratory table or desk.

Burma Surgeon. By Gordon S. Seagrave, M.D. 8°, cloth, 295 pp., with 22 illustrations and frontispiece. New York: W. W. Norton & Company, Incorporated, 1943. \$5.00.

This book, one of the best sellers of 1943, hardly needs any introduction to the medical profession. It is an outstanding book of the war by a man whose personality is stamped on every page.

To a missionary doctor in Burma came an opportunity as the result of the war to do a job far greater than anything he had anticipated when he went to his station. Fortunately for the world and for the British and American troops involved, Dr. Seagrave proved to be a man of exceptional quality. He not only had excellent surgical judgment but also knew how to administer an organization and train its personnel. He took the native women and taught them to be first-class nurses. When General Stilwell and his army had to retreat, Dr. Seagrave became one of the outstanding members of that memorable march.

This book, if not already read by every member of the profession, should not be missed.

Exploring the Dangerous Trades: The autobiography of Alice Hamilton, M.D. 8°, cloth, 433 pp., with 7 illustrations and frontispiece. Boston: Little, Brown and Company, 1943. \$3.00.

Dr. Hamilton is one of the great pioneer physicians of this country, and her autobiography is an unusually striking contribution. Her early life during the last decade of the nineteenth century was spent in Chicago, where she was associated with the pioneer social experiment at Hull House. There she came in contact with poverty, disease and particularly industrial accidents, and from this background, plus an adequate knowledge of pathology, a subject that she taught for many years at Northwestern University, Dr. Hamilton became an authority on diseases associated with workmen and working conditions. She made an extensive survey of Illinois, pioneering and exploring an almost unknown field. Later, this was extended into a federal survey of "dangerous trades," with final extension to Europe. Ultimately, she became a member of the staff of the Harvard Medical School, where she continued her work for many years. In 1935, having become a professor emeritus at Harvard, she retired to Connecticut, where she lives quietly in the country, occupied with her writing.

The book is a delightfully written, simple, straightforward story of a woman who has made distinct additions to the knowledge of industrial diseases. All through her account one feels that she is an extremely human character, with a personality that must have appealed to a great many people. She writes pleasantly about her associates and neighbors, and the book is of unusual interest, as well as a stimulating experience.

The Kenny Concept of Infantile Paralysis and Its Treatment. By John F. Pohl, M.D. In collaboration with Sister Elizabeth Kenny. With a foreword by Frank R. Ober, M.D. 8°, cloth, 386 pp., with 100 illustrations. Minneapolis: Bruce Publishing Company, 1943. \$5.00.

This book has the official sanction of Sister Kenny, since she collaborated with the author in writing it. It is, therefore, an up-to-date discussion of the technic advocated by Sister Kenny, with a plan of the relief of pain and muscle spasm in poliomyelitis by the early and continued use of hot packs, as well as the procedure designed to re-educate the neuromuscular system. The application of moist heat is not a new one, since it was advocated as early as 1916 by Lovett and his co-workers. Sister Kenny's contribution in part has been the application of this form of treatment early in the course of the disease — as soon as the diagnosis has been made.

The first part of the book deals with this period of the disease and is fully illustrated with photographs and diagrams, showing the details of the Kenny technic. The second part covers the convalescent stage of the disease and is also fully illustrated. Finally, the third section is concerned with the treatment of patients in the chronic stage.

This text, with its many illustrations, is fundamental for an understanding of the Kenny concept of the treatment of infantile paralysis and should be in the hands of everyone concerned with the care of patients with this disease.

A History of Tufts College Medical School: Prepared for its semi-centennial 1893-1943. By Benjamin Spector, M.D. 8°, cloth, 414 pp., with 49 illustrations. Boston: Tufts College Medical School Alumni Association, 1943. \$5.00.

As a medical historian, the author is to be complimented for his singularly lucid and succinct semicentennial story of the Tufts College Medical School. Beginning with the removal of the restriction in the original Tufts College charter, which prevented the conferral of medical degrees, he describes from original sources the establishment of the school on October 4, 1893, and sketches by decades its course to the present time. Many of these documents are reproduced in facsimile. There are illustrations of the several buildings of the school, and many reproductions of graduation and other programs. Particularly valuable are the sketches of the original seven founders and the biographies of other distinguished Boston physicians of the epoch. This well-documented volume constitutes an enduring and worthy record of the first half century of one of the leading New England schools of medicine.

Kinetic Bandaging including Splints and Protective Dressings: The kinetic method of visual teaching. By Seymour W. Meyer, M.S., M.D. 8°, cloth, 310 pp., with 540 illustrations. Philadelphia: F. A. Davis Company, 1943. \$3.50.

The present is a good time to emphasize the importance of knowing how to apply a bandage, particularly since too little attention in recent years has been paid to this art. The primary purpose of bandaging, when employed as a final step in a surgical operation, is to secure a dressing in contact with the operative incision, but there are other quite as important services that a bandage may provide. This book, through its well-planned illustrations, could make a skilled bandager out of the veriest tyro. The methods of using adhesive plaster and the utility of the triangular bandage are equally well outlined.

The book should find a place in the hands of everyone who needs to be familiar with the application of surgical dressings. The success of an operation in some cases and the comfort of the patient in most cases are largely influenced by the skill with which a bandage is applied.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Lectures on Peace and War Orthopedic Surgery. Selected from the instructional courses presented at the eleventh annual assembly of the American Academy of Orthopaedic Surgeons, Chicago, January 17, 18, 19, 20 and 21, 1943. Edited by James E. M. Thomson, M.D., chairman of the instruc-

tional section. 4°, cloth, 322 pp., illustrated. Ann Arbor, Michigan: Edward Brothers, Incorporated, 1943. \$4.00.

This volume forms the transactions of the instructional section of the 1943 meeting of the American Academy of Orthopedic Surgeons. The volume contains sixty-five papers by military and civil medical authorities and is illustrated with half-tone reproductions of x-ray films and drawings which are reproduced by photolithography.

Physiology of the Nervous System. By John Farquhar F.C.M.A., D.Phil., D.Sc. (Oxon.), S.B., M.D. (Fav.). 8th edition, revised and reset. 8°, cloth, 614 pp., with 112 illustrations. London: Oxford University Press, 1943. \$9.00.

The reviewer believed that the first edition of this work was an outstanding contribution to the subject; his opinion is reinforced by the appearance of the second edition, thoroughly revised and brought up to date. The book can be highly recommended to medical students, physicians, workers in laboratories and libraries. It is, indeed, a fundamental text that should find a place on the shelf of all medical libraries, both public and private.

The Arthropathies; A handbook of roentgen diagnosis. By Alfred A. de Lormier, M.A., M.D., colonel, Medical Corps, United States Army, and commandant, Army School of Roentgenology, Memphis, Tennessee. 8°, cloth, 319 pp., with 678 illustrations. Chicago: The Year Book Publishers, Incorporated, 1943. \$5.50.

This handbook is a compilation of lectures presented by the officers of the Army Medical School in Washington and the Army School of Roentgenology in Memphis. The material is presented in the form followed in the teaching, which is largely graphic. There are a large number of roentgen plates.

Human Constitution in Clinical Medicine. By George Drap M.D., associate professor of clinical medicine, College of Physicians and Surgeons, Columbia University, and associate attending physician, Presbyterian Hospital, New York City; C. W. Dupertuis, Ph.D., physical anthropologist, Constitution Clinic, Presbyterian Hospital, New York City; and J. L. Caughey, Jr., M.D., Med.Sc.D., associate professor of medicine, College of Physicians and Surgeons, Columbia University, and assistant physician, Presbyterian Hospital, New York City. 8°, cloth, 273 pp., with 29 illustrations and 30 tables. New York: Paul B. Hoeber, Incorporated, 1943. \$4.00.

This manual is designed for the use of medical students and is written from the clinical point of view, with the objective of showing that there is an essential relation between each patient and the disease that at any moment he or she may suffer.

Psychosomatic Diagnosis. By Flanders Dunbar, M.D., M.Sc.D., Ph.D., member, Department of Medicine and Department of Psychiatry, Columbia University. With a foreword by Leonard G. Rowntree, M.D., colonel, Medical Reserve Corps, United States Army, and chief, Medical Division, Bureau of Selective Service of the War Manpower Commission, Washington, D. C. 8°, cloth, 741 pp., with charts and 12 tables. New York: Paul B. Hoeber, Incorporated, 1943. \$7.50.

This new treatise in a new field of medicine has been written for the use of the general practitioner and also serve as a guide in teaching. Emphasis has been placed on the fundamental importance of a complete case history after which special chapters are devoted to fractures, cardiovascular disease, rheumatic disease, cardiac arrhythmia and diabetes. A large number of clinical case histories are included in the text; also there is appended a large bibliography.

The Philosophy of Marsilio Ficino. By Paul O. Kristeller, associate in philosophy, Columbia University. Translated into English by Virginia Conant. 8°, cloth, 441 pp. New York: Columbia University Press, 1943. \$4.50.

This book was originally written in German in 1937, and the translation is the first study in English of Ficino, who was a physician and leader of the Platonic Academy in Florence.

TULAREMIA IN NEW ENGLAND

A Review of Eighteen Cases, with the Report of Two Additional Cases

FRANCIS D. MOORE, M.D.,* CARL S. SAWYER, M.D.,† AND S. GILBERT BLOUNT, JR., M.D.‡

BOSTON, MASSACHUSETTS, AND PROVIDENCE, RHODE ISLAND

THE term "tularemia" has been applied to a wide variety of illnesses due to human infection by *Pasteurella tularensis*. The most frequently occurring clinical picture is that of an open ulceration with regional lymphadenopathy and evidence of a severe systemic infection that appears to be out of proportion to the local lesion. This ulceroglandular form of the disease may be accompanied by mucocutaneous involvement, rash or enlargement of the spleen. The infection may also produce a form of the disease in which the systemic factors entirely outweigh the local lesion, in which event the typhoid form of the disease is found. The organism responsible for this infection is apparently endemic in a fairly widespread animal reservoir and is transmitted from animals to human beings either by an insect bite, by direct handling or by ingestion of infected animal material.

The ulceroglandular form of tularemia so closely resembles various trivial nonspecific peripheral infections and infected lacerations that it is often overlooked. Furthermore, the local lesion may be so minor as to be completely overshadowed by the systemic manifestations, leading to a mistaken diagnosis of blood-stream infection with gram-negative bacilli such as the typhoid bacillus or a febrile illness such as brucellosis, rheumatic fever or subacute bacterial endocarditis. It is therefore necessary to stress the importance of this disease in differential diagnosis and the need of an exhaustive search for a possible local lesion in the presence of fever of unknown origin. Because of these facts, as well as the appearance of 2 recent cases in New England, it has seemed worth while to review the history of tularemia in New England, bringing the literature on all the available cases up to date.

New England appears to have been the last region of the United States to remain free of infection with *Past. tularensis*. By 1932, tularemia

had appeared in all the states of the Union except Maine, Vermont and Connecticut¹; New England could claim the fewest cases of any sizable region in the country and contained the only three case-free states. Since that time, cases have appeared in New England at the rate of approximately 2 a year, and at the present time it is possible to bring together a total of 20 cases. Vermont remains as the only state apparently free of the disease.

Whether this phenomenon is due to an increasing incidence of tularemia in the region or merely to increasing recognition and bacteriologic confirmation is an academic question that cannot be answered on the basis of the material at hand. Although the disease was first described in animals, in California, by McCoy and Chapin in 1911,^{2,3} there is no way of knowing how widespread the animal reservoir was at that time. In 1919 Francis⁴ described the human disease as occurring in Utah, approximately five hundred miles from Tulare County in central California, where McCoy and Chapin had discovered the micro-organism seven years before. This geographical trend, however, is difficult to evaluate in the light of the fact that by 1938 over 1000 cases had been reported⁵ from Russia, apparently contracted from the skinning of water rats, and many other cases had been found in Japan, Norway, Canada, Sweden and Austria. By these data one is forced to the conclusion that although American in origin, scientifically speaking, the disease is of world-wide distribution.

In the light of these facts it is interesting that one region in America should apparently stay free of tularemia until 1929. Furthermore, the grouping of the New England cases indicates that factors of importation, either of rabbits or of infected human beings, seem still to be operative in the spread of the disease. This corroborates the impression that tularemia is still a relatively new disease in New England, not only to human beings but also to animals.

These factors of importation concern firstly 3 patients in the Boston area, one who contracted the

*Assistant in surgery, Massachusetts General Hospital, and instructor in surgery, Harvard Medical School, Boston

‡Intern, Medical Service, Rhode Island Hospital, Providence, Rhode Island

disease in Colorado and then came to Boston, a second who contracted it from tick bites while in Georgia and a third who contracted it from a rabbit shot in Illinois and shipped here. Furthermore, in 1936, cottontail rabbits were imported from the West and released near Falmouth, Massachusetts, and within two years 3 cases had been reported from that district. A fourth case occurred in the region of Falmouth in 1943. This makes a total of 7 cases in New England — nearly a third of the entire series — directly traceable to importation of infected animals or contracted elsewhere. It is impossible to say to what extent these importations have influenced the further spread of the disease in New England, but the fact that 4 more cases have occurred within seventy miles of the Falmouth area is suggestive.

CHRONOLOGICAL REVIEW OF NEW ENGLAND CASES

The first case to appear in New England was reported from Massachusetts by Withington.⁶ The patient contracted the ulceroglandular type of disease from tick bites while visiting on an island off the coast of Georgia in 1929. He had a septic abrasion on the scrotum, with an enlarged inguinal node that subsequently suppurated, and x-ray evidence of a slight pneumonitis on the left side. Widal and Wassermann reactions were negative, but the serum agglutinated *Past. tularensis* in a dilution of 1:1280 and *Brucella abortus* in a dilution of 1:160 (partial agglutination in a dilution of 1:320). Randall⁷ in 1929 reported a case in Rhode Island in which a man contracted tularemia after handling three dead rabbits. A cat that ate one of the rabbits also contracted the disease and died. Agglutination of the patient's serum against *Past. tularensis* was positive. The second case to appear in Massachusetts⁸ occurred in Boston in 1929. The patient evidently caught the disease from a cold-storage rabbit that had been frozen for thirty days and imported from Illinois. The patient had ulceroglandular tularemia with an urticarial eruption, and serum agglutination against *Past. tularensis* was positive in a dilution of 1:640.

Badger⁹ and Eckstein¹⁰ both referred to 2 cases, one occurring in New Hampshire in 1931 after the handling of rabbits and the other in Maine in 1933 after the skinning of a fox. Further details on these cases have not been found elsewhere in the literature, but the second one has been confirmed by the Maine Department of Health and Welfare.¹¹ The disease in this case was of the ulceroglandular form and was fatal. It was proved by autopsy, culture and agglutination.

In 1934,¹² a man contracted the ulceroglandular form of tularemia from the ingestion of a rabbit that he had killed on a ranch in Colorado. He returned to Boston after his symptoms had appeared and was hospitalized. Serum agglutination

was positive in dilutions up to 1:1280, and a test with the Foshay tularemia suspension was positive.

In 1935 and 1936, 3 cases were reported to the New Hampshire Department of Health.¹³ All three were clinically stated to be tularemia and accepted as such by the state authorities, but the detailed bacteriologic report are not available.

In 1937,⁹ a ten-year-old girl developed a typhoidal type of tularemia in Falmouth, without skin lesions or adenopathy, presumably from the saliva of her dog, which became ill three days later. Specific agglutination was positive in dilutions 1:1280. The dog serum was positive in dilution up to 1:40. This case appeared three months after Western cottontail rabbits had been released in the neighborhood of Falmouth. In the same district, one year later, another child developed ulceroglandular tularemia after being bitten by a tick. The bite was in the scalp and was accompanied by enlarged postaural nodes. Serum agglutination tests were not done. A Roxbury resident visiting Cape Cod in July, 1939, was bitten on the thigh by a tick, subsequently developing ulceroglandular tularemia with pneumonic symptoms.¹⁴ This patient, unlike the others, had severe systemic disease and serum agglutination tests were positive in dilutions up to 1:1280.

Gibbons, Lamoureux and Arkless¹⁵ described a case in Connecticut that occurred in December 1940. After killing and dressing three rabbits the patient developed tularemia with a finger ulcer, chills, fever and adenopathy, which subsided in three days. A relapse eleven days later with severe systemic disease proved fatal. Agglutination tests were positive in dilutions of 1:640.

In 1941, a man in Lawrence, Massachusetts, complained of an abrasion on his finger that subsequently became necrotic. The diagnosis of tularemia was established by history of exposure to rabbits that he had shot and dressed, as well as by the findings of adenopathy, chills, fever and a specific agglutination test in serum diluted to 1:640.¹²

A second case was reported from Rhode Island by Eckstein¹⁰ in 1941. The patient had the ulceroglandular form of the disease, contracted after dressing a rabbit that he had shot. The primary lesion appeared in a puncture wound of the hand sustained two days before. Specific agglutination was positive in serum dilutions up to 1:2560. This patient received sulfanilamide therapy.

Two other cases were reported from Connecticut in 1941. The first of these¹⁶ occurred in Columbia only ten miles from Colchester, where the previous Connecticut case had occurred.¹⁵ This was a fatal case of ulceroglandular tularemia, with pneumonic manifestations, contracted from a cat bite. The second was a case of ulceroglandular tularemia from handling rabbits,¹⁷ it occurred in Stamford. Agglutination tests were positive in a titer of 1:80.

The most recent New England case to appear prior to the 2 reported below was a fourth case from Falmouth district,¹² following a tick bite. The patient developed right-sided pneumonia without evidence of a primary lesion or adenopathy. Specific serum agglutination tests were positive.

REPORT OF CASES

CASE 1. The patient (M. G. H. Unit 405941) was a 52-year-old inhabitant of Waltham. He was admitted to the Emergency Ward on June 8, 1943, and stated that 3 weeks prior, while working in his garden, he had been bitten over the upper sternum by a small insect. He had not noticed the bite until he went into the house and looked in a mirror. He did not identify the insect, but when he removed and shed it, it appeared to be distended with blood and to have a hard shell.

For 3 days nothing further was noted about the incident. The end of that time the patient began to notice occasional chilly sensations, fever and considerable muscular weakness. Following a week of such symptoms, not severe enough to incapacitate him, he noticed soreness in the left axilla and a small papule at the site of the bite, which broke down and formed an ulcer that gradually increased in size. He poulticed the lesion and called in his physician, who gave him sulfadiazine totaling 3 gm. a day for 10 days. Since the fever and malaise persisted, as well as the ulcer and the sore in the left axilla, he was referred to the hospital.

On entry to the Emergency Ward the patient had a temperature by mouth of 101.8°F. and a white-cell count of 14,400. The urine was negative. The ulcer over the manubrium was 1.5 cm. in diameter, with a 3-cm. zone of erythema surrounding it. It was not tender and there was no undermining or penetration, but the edge was indurated. Little exudate was present, it was not granulating, and there was no evidence of undrained pus. A firm, tender, freely movable lymph node the size of a walnut was present in the left axilla. The patient had had no contacts with rabbits, ground squirrels or other rodents and the only small animals he had seen around his garden were chipmunks.* He did not remember seeing any that appeared ill, and no dead ones had been seen to his knowledge.

Tularemia was suggested as a tentative diagnosis, and the patient was admitted to the hospital. Primary syphilis, staphylococcus-streptococcus infection, anthrax, sporotrichosis and other mycotic infections were also considered. A blood culture yielded no growth, and serum agglutination tests against *Past. tularensis* done on admission were negative in all dilutions. Cultures from the ulcer, taken in the usual aerobic and anaerobic media, showed a coagulase-negative hemolytic *Staphylococcus albus*, diphtheroids and aerobic spore-formers. In addition, some yeasts were found that were cultured and studied for virulence by mouse injection, with negative results. Dark-field examination of the material from the ulcer for *Treponema pallidum* was negative. His blood serum gave a positive Hinton and a negative Wassermann reaction on two occasions. A Hinton test the day before discharge was negative. Agglutination tests for typhoid and paratyphoid fever were negative. Stool and urine cultures were negative.

The clinical course was one of continued swinging fever, with a high as 103.6°F., for the first 10 days in the hospital. The patient had few symptoms other than malaise. The white-cell count fell to 6000 by June 22 and he consistently showed a high monocyte percentage. He developed a node in the left axilla on June 11, and for 3 days thereafter he had generalized lymphadenopathy, the nodes being almond-sized, nontender and freely movable. There was no rash.

On June 21, to obtain material for histologic study to clarify the diagnosis, the ulcer was excised under Pentothal sodium anesthesia and the wound was closed with silk. The operative site healed cleanly, and the temperature immediately became normal and remained so until discharged 7 days later. The palpable nodes disappeared in 4 days.

*It is of interest in this connection that Zinsler¹³ states that chipmunks are among the more susceptible group of animals to infection with *Past. tularensis*. Welch and Jakmauh¹⁴ point out that the chipmunk is also one of the common hosts in this region for the wood tick *Dermacentor variabilis*.

The pathological report from the excised lesion was "acute and chronic inflammation," with no changes characteristic of either syphilis or other specific granulomas. Blood serum taken for heterophile agglutination on the same day as the operation was negative.

A repeated agglutination test for *Past. tularensis* showed the following results: serum diluted 1:20, +++; 1:40, +++; 1:80, ++; 1:160, ++; 1:320, ++. This positive agglutination, in the presence of a clinical picture compatible with the disease, established the diagnosis of the ulceroglandular form of tularemia. The fact that the earlier agglutination test was negative was attributed to its being taken too early, although the patient was in his 3rd week of the disease. He was discharged home on the 7th postoperative day. He was seen 6 months later and was in excellent health. Blood Hinton and Wassermann reactions were negative on two occasions at about that time. Serum agglutination tests of *Past. tularensis* were still positive in dilutions up to 1:320.

CASE 2. The patient (Rhode Island Hospital 375228), a 36-year-old loom fixer, entered the Rhode Island Hospital on November 16, 1943. For 4 days prior to the onset of his illness on October 28, he had spent part of the day hunting rabbits; he had killed ten, skinning and dressing them himself. At the time, he had a hangnail on the left thumb, and 1 day after the onset of the systemic illness the thumbnail became infected and the inflammation persisted despite treatment.

On the day of onset of his illness the patient was awakened at about 2 a.m. by chills and chilly sensations that continued the rest of the night. Alternating with the chills, he felt warm, perspired copiously and had a severe headache. The next day he noticed the infection near the left thumbnail, and within a short period of time observed sore lumps in the left axilla "as big as eggs." He called in his physician, who noted that he had a temperature of 104.5°F. For the 11 days until entry to the hospital, this fever continued rising, to 102 or 103°F. daily. Eight days prior to entry the patient developed a cough productive of moderate amounts of yellowish-white sputum without blood. This febrile illness, with malaise, headache, cough and the infected thumb and axillary nodes, continued up to entry.

On admission the patient had a temperature of 102°F. but did not appear acutely ill. Inspiratory rhonchi and wheezes were heard over the chest, with occasional rales at the left base. There was an ulcer at the angle of the nailbed of the left thumb that oozed serum, had black ragged edges, was tender and was surrounded by a tender area larger than the ulcer itself. There was a left epitrochlear node, and a plum-sized axillary node, both of which were nontender. The white-cell count was 14,700, with 43 per cent lymphocytes. A diagnosis of ulceroglandular tularemia was made, and the possibility of pneumonic involvement was raised. An x-ray film of the chest showed patchy density in both lobes compatible with bronchopneumonia. Agglutination tests done at the Rhode Island State Department of Health were positive against *Past. tularensis* in dilutions up to 1:80. Agglutination against brucella was negative.

On the 4th hospital day, with the patient continuing to run a temperature of 102 to 103°F. daily, sulfamerazine was given, beginning with a dose of 5 gm., followed by 1 gm. every 8 hours. After 3 days of treatment there was some improvement, but not until the 6th day did the temperature drop to normal. Coincident with this fall the pulmonary lesion cleared, and serum taken at that time was positive in titers up to 1:1280 and 1:2560. The thumb lesion was still unhealed and the axillary node was still enlarged and tender, with overlying redness in the skin. The patient was discharged 4 days later.

One week after discharge, the axillary node broke down and was incised and drained, and after 1 month it was slowly healing.† On December 21, 3 weeks after discharge and 2 months after onset, the agglutination tests against *B. tularensis* were positive in dilutions up to 1:2560.

During the hospital stay, cultures from the ulcer were injected into guinea pigs, which died and showed gross lesions characteristic of *Past. tularensis* infection. Bits of liver and spleen were cultured on cystine agar in an effort to isolate the organism, but the cultures were lost and the organisms were not finally identified.

†We are indebted to Dr. Wallace Lisbon, of Providence, Rhode Island, for information concerning the course of the patient after discharge.

DISCUSSION

Francis²⁰ has done much of the work on the etiology, transmission and animal vectors of tularemia, and his work should be consulted for these matters. A recent article by Foshay²¹ covers the clinical aspects, methods of early diagnosis and results of serum treatment. No attempt to review the literature will be made here.

Transmission from animals to man by insect bite is not uncommon.¹ The insect in Case 1 was most

known. One was the result of a cat bite, 1 of skinning a fox and 1 of handling an infected dog, and 3 were of unknown modes of transmission.

Of the 20 New England cases, 3 were fatal. One of the fatal cases was a pneumonic relapse from the ulceroglandular form¹⁵; the second showed a form of tularemia involving the lungs but apparently concomitant with an ulceroglandular lesion and at autopsy, lesions throughout the body¹⁶; in the third the disease was of the ulceroglandular variety

TABLE 1. Summary of 20 New England Cases of Tularemia.

YEAR	LOCALE	ANIMAL SOURCE OR INSECT VECTOR	TYPE OF LESION	BACTERIOLOGIC CONFIRMATION	OUTCOME	REFERENCE
1929	Boston (acquired in Georgia)	Tick	Ulceroglandular	Agglutination (1:1280)	Recovery	Withington ⁶

likely the tick *Dermacentor variabilis*, which has previously been reported as the vector of Rocky Mountain spotted fever in New England.²² The tick *Dermacentor andersoni*, which is rarer in the eastern United States, may have been involved. The biting season of these ticks is from March to July. The other insect that carries the organism of tularemia is the horsefly, *Chrysops discalis*, which is active from June to September.

Many different animals have been found to be infected with tularemia, and the infection may be passed directly by handling or ingestion of the flesh, as well as by the parasites that are found on the infected hosts. Of the 20 New England cases, 9 involved direct handling of rabbits and 5 were traceable to tick bites, with the animal host un-

known. A tabular compilation of the pertinent data on the 20 cases is presented in Table 1.

Early diagnosis may sometimes be established by injecting material from the ulcer into a guinea pig, and then transferring bits of the necrotic foci in the liver and spleen to a cystine-containing medium.¹ The patient's blood culture may also be positive early in the disease, but again the organisms can usually be recovered only by animal passage. Francis²⁰ has pointed out that direct smear and culture are unavailing. Agglutination tests usually become positive from the third to the sixth week of the disease.

Foshay²¹ has described intradermal tests with suspensions of killed organisms in phenolized saline solution, which are read in forty-eight hours and

positive during the first week of the disease. It is also devised an intradermal test using anti-tularemia which is read in fifteen minutes and in one case has been reported positive as early as eight hours after the initial chill, but results have not been so successful as those with the vaccine. Foshay also developed an antiserum from goats and reported the results of treatment in 600 cases.

Case 1, the patient showed a false-positive skin test on two occasions. Six months after recovery, the serologic reaction was negative. Such a finding has not previously been reported, and its significance must await reports of other cases. Francis and Nagle²³ give the results of eighty-seven skin tests on 64 patients with tularemia; only "doubtful" reaction was obtained.

The response of the Massachusetts patient (Case 2) to primary excision of the ulcer was striking, and the results of this method are corroborated by other observers it may constitute a useful way of shortening the period of disability from the disease. He did not respond to sulfadiazine. An analysis of the response of the Rhode Island patient (Case 2) to a sulfonamide is difficult, since the dependence of temperature required six days after giving the drug.

SUMMARY

Eighteen cases of tularemia occurring in New England are reviewed. Of these, 8 have not previously been available in the literature. To these are added the detailed data on 2 New England cases, occurring in Massachusetts and 1 in Rhode Island during the summer and fall of 1943.

The mortality for this group of 20 cases was 15 percent.

Vermont remains as the only state in the Union where tularemia is endemic.

The false-positive Hinton test was a feature of the Massachusetts case. Clinical subsidence following excision of the ulcer was also an unusual feature of this case.

The Rhode Island case was one of ulceroglandular tularemia contracted from handling rabbits. In addition to local and lymph-node lesions, the patient

developed definite evidence of pneumonic involvement.

We are indebted to the following state officials for their willing aid in gathering together these data on tularemia throughout New England:

- Dr. Mary M. Atchison, acting state health officer, New Hampshire State Board of Health
- Dr. Charles F. Dalton, secretary and executive officer, Vermont Department of Public Health;
- Dr. Roy E. Feemster, director, Division of Communicable Diseases, Massachusetts Department of Public Health;
- Dr. Roscoe L. Mitchell, director, Maine Department of Health and Welfare;
- Dr. Stanley H. Osborn, commissioner, Connecticut State Department of Health; and
- Dr. William P. Shields, epidemiologist, Division of Communicable Diseases, Rhode Island Department of Health.

VITAMIN B DEFICIENCY IN PRIVATE PRACTICE*

DUDLEY MERRILL, M.D.†

CAMBRIDGE, MASSACHUSETTS

PURE, uncomplicated diseases caused by deficiency of vitamin B—pellagra, beriberi, ariboflavinosis, polyneuritis and the Wernicke syndrome—are a great rarity in New England. This is probably true in most geographical areas where famine is unknown and the dietary habits of the majority of the people are not rendered grossly inadequate by poverty or by the lack of coarsely ground cereals, green vegetables, dairy products and meat. Occurring as complications of many different types of disease, however, these diseases are being recognized with increasing frequency and are actually of far greater importance clinically, outside the endemic areas of pellagra and beriberi, than are their uncomplicated forms.

Cowgill¹ demonstrated that the tendency to develop symptoms of vitamin B deficiency varies with the metabolic rate of the body and inversely with the vitamin B intake, and that the body weight and metabolism are consequently the most important factors determining the vitamin requirement. From these fundamental laws he was able to predict or explain the clinical occurrence of vitamin B deficiencies in association with many widely different types of disease. Shattuck,² Wechsler,³ and Minot, Strauss and Cobb⁴ had already reported beriberi complicating polyneuritis in patients suffering from profound nutritional disturbance, either alone or as a complication of many types of chronic illness. Strauss and McDonald⁵ had also pointed out that the polyneuritis of pregnancy, previously attributed to a hypothetical toxin, is in all probability merely another example of polyneuritis due to a nutritional deficiency. In a later paper, Strauss⁶ elaborated on the importance of disturbance of the gastrointestinal tract as a conditioning factor in the production of deficiency states. Weiss and Wilkins,^{7,8} reported beriberi heart disease as not infrequent in patients suffering from nutritional deficiency.

From the work of all the above authors it has become apparent that clinical manifestations of vitamin B deficiency should be searched for in any situation in which there is an increased metabolism, with or without an obvious deficiency of vitamin B in the diet or a disturbance of the function of the gastrointestinal tract. This may arise because of increased muscular activity, increased caloric intake, fever, hyperthyroidism, long-continued vomiting, diarrhea or dietary restriction.

It is unfortunate that in this group of cases there is great danger of overlooking the earliest symptoms

and signs of impending deficiency disease because of the frequently far greater importance of the precipitating factor—pneumonia, malaria, cirrhosis of the liver, pregnancy and so forth.

Many authors have stated that the earliest manifestations of vitamin B deficiency are easily reversible if proper therapy is instituted, whereas later process may progress to a stage of slow reversibility or nonreversibility in spite of substitution therapy.

I⁹ have already reported 3 cases of severe dysphagia associated with profound nutritional deficiency, 1 of them mistakenly diagnosed as carcinoma of the esophagus, all of which responded to substitution therapy. In retrospect the response to therapy—perhaps be explained by the short duration of symptoms.

Goldsmith¹⁰ searched for evidences of riboflavin and niacin deficiency in a series of 200 consecutive patients admitted to the medical services in the Charity Hospital in New Orleans; these consisted of 50 white women and 50 Negroes, and 50 white men and 50 Negroes. She found 79 cases of definite and 54 of probable deficiency disease in this unselected series. It may be considered by some of her criteria for diagnosing these deficiency syndromes were slightly overgenerous, but there can be no doubt that these diseases were of far greater prevalence in this particular group of charity patients in a Southern city than even most nutrition experts would have expected.

Because of the frequency with which cases of vitamin B deficiency of moderate or severe nature have appeared in private practice in the metropolitan area of Boston, it has seemed worth while to report some of them. These diseases are not limited to any special group,—to the natives of Labrador or the Orient, sharecroppers, chronic alcoholic addicts or the inmates of a city hospital. Furthermore, they are common complications of many serious illnesses, and their recognition is not purely of academic interest. The therapeutic implications are obvious.

CASE REPORTS

CASE 1. C. J. M., a 63-year-old widow, was first examined because of asthma, cough and vomiting. Three days previously she had had severe chilly sensations, cough and a pain in the chest. Asthma, which she had had off and on for 25 years, returned. For 3 days she had vomited practically everything she had eaten. A year and a half before this episode she had been diagnosed as having malnutrition and dactylitis, but in spite of much dietary advice she had failed to put on any weight.

Physical examination revealed a temperature of 103°F., a pulse of 120 and a blood pressure of 130/80—18 months previously it had been 200/110. The lungs were full of asthmatic rales, but there was a patch of pure bronchial breathing over a small area of the right upper lobe anteriorly.

*From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

†Instructor in medicine, Harvard Medical School; junior visiting physician, Boston City Hospital; associate physician, Cambridge Hospital.

The patient was hospitalized at once. The sputum contained Type 2 pneumococci, and x-ray examination of the chest showed consolidation in the right midlung. The blood protein nitrogen level was 67 mg. per 100 cc. but fell to 7 mg. 2 days later. Sulfathiazole was given for 3 days, the temperature fell to normal in 24 hours. Five days after admission she developed urinary retention, with a nonprotein nitrogen of 75 mg., and exhibited considerable mental confusion. For the next 3 days the patient was repeatedly catheterized and fluids were given in large quantities, but the nonprotein nitrogen level rose to 100 mg. and she developed sacral and pulmonary edema, with profuse sputum and a beefy-red tongue. She was given 100 mg. of nicotinic acid every 3 hours and 2 cc. of mercupurin intravenously, and fluids were limited to 2000 cc. every 24 hours. An indwelling catheter was placed in the bladder. Twelve days after admission the nonprotein nitrogen level had fallen to 25 mg. and the temperature to below 100°F. The patient was well oriented, the edema had disappeared, and the tongue was practically normal. The bladder control did not return to normal for another 4 weeks. The patient was discharged 6 weeks after admission.

This sixty-three-year-old undernourished, asthmatic woman developed pellagra ten days after the onset of pneumonia and five days after the temperature had returned to normal. She finally recovered from both the pellagra and the pneumonia.

Of considerable interest is the fact that she survived a second attack of pneumococcal pneumonia exactly two years after the one reported here. She was treated with sulfadiazine and large amounts of vitamin B complex from the onset, and experienced no complications.

CASE 2. M. P., a 68-year-old edentulous widow, was seen because of an extremely sore mouth. One month previously she had had pneumonia with moderately severe jaundice. She had received no serum, and sulfonamide drugs had been withheld because of the jaundice. She ran a course characteristic of pneumonia and improved. The temperature became normal 16 days after the onset of the pneumonia. Twenty days after onset, she first complained of a sore mouth. A severe stomatitis was noted and sulfanilamide was prescribed. Three days later the mouth was full of so-called "Vincent's lesions," which were painted with 10 per cent chromic acid.

When I first saw the patient 12 days after the onset of stomatitis, the tongue was smooth, moist and fiery red along the edges. Toward the back there was a sharp line where the exfoliation had apparently stopped. There were two ulcers 3.5 cm. in diameter inside the right cheek and extending over the toothless lower gum. They were filled with blackish slough, the result of cauterization with chromic acid. The entire mouth and lips were extremely sore, and there were several small ulcers in both tonsillar regions and on the floor of the mouth. There was no dermatitis of the hands or legs, and no neuritis. A diagnosis of stomatitis due to acute vitamin B deficiency secondary to pneumonia was made, and the patient was started on 100 mg. of nicotinic acid and 4 brewer's yeast tablets three times a day. Local treatment was limited to a saline mouthwash.

Eleven days after the beginning of vitamin therapy the stomatitis had improved strikingly, although the left side of the throat was still sore. The ulcers inside the right cheek were one third their former size, and those in the tonsillar regions and on the floor of the mouth were clean and beginning to heal. The patient had some difficulty in mental concentration, some numbness of the right leg and soft and pitting edema of both legs up to the knees. At that time it was discovered that she had had peculiar dietary ideas for some years, having avoided all meats, drunk little milk and eaten only a few eggs for months, if not years, before the onset of pneumonia. Additional diagnoses of peripheral neuritis and probable protein deficiency were made, and the patient was urged to alter radically her eating habits.

When last seen 6 days later, the patient was feeling much better. The throat and mouth were no longer sore and she

was eating well. She was having less difficulty with mental concentration, all the ulcers in the mouth were healed except one inside the right cheek, which was still 1 cm. in diameter, and the edema and the numbness of the right leg had disappeared.

This elderly edentulous woman with peculiar eating habits developed clinical pellagra, beriberi and probable protein deficiency following a moderately severe pneumonia. It seems likely that if the course of the pneumonia had been cut short by either drug or serum therapy, — jaundice complicating pneumonia is now known not to be a contraindication for either, — she might never have manifested outspoken signs of vitamin B or protein deficiency, in spite of her inadequate dietary and poor dental equipment.

CASE 3. P. R., a 47-year-old, married woman of a slender, apprehensive type, was seen because of metrorrhagia. A uterine curettage 2 months later showed hypertrophic endometrium but no signs of malignancy. A hysterectomy was performed. Five days after operation the patient began to be nauseated and vomited several times. This continued for several days and the patient became extremely depressed. She had eaten almost nothing since the operation. The temperature had remained flat the first week after operation, never going above 99.6°F., but the pulse had slowly risen to 110. The patient was dehydrated, but the tongue aside from being dry appeared perfectly normal, being neither sore nor red. The possibility of vitamin deficiency and gastric dilatation was raised. Thiamin chloride and intravenous glucose and saline solutions were started and a tube was inserted in the stomach. One thousand cubic centimeters of black, foul-smelling liquid was removed and the patient felt better. The next day she had several loose stools and the tongue was still dry, so that more intravenous glucose and saline solutions were given. Another gastric lavage produced a large amount of green, foul-smelling fluid.

Nine days postoperatively, diarrhea was well established and the administration of 100 mg. of nicotinic acid every 4 hours was begun. On the 4th day, the patient looked better and the nausea, vomiting and diarrhea had stopped, but the mucous membranes of the entire inside of the mouth and tongue began to peel off. From time to time she was confused, irritable and difficult to handle, being extremely suspicious of visitors, nurses and doctors.

By the 12th day, the mental state seemed to be clearing, although the patient was still having three or four loose stools a day and occasionally vomited undigested food. By the 14th day she seemed mentally normal, the diarrhea had diminished to one or two loose stools a day, and vomiting had ceased. The temperature was normal and the pulse 90, and the oral mucous membranes were no longer fiery red or sore.

The patient again became psychotic on the 17th day, refusing all medication. On the 20th day, although progressing satisfactorily, she was still restless at night and developed an itching, erythematous eruption of both shins and the skin at the base of the neck. The lips were still dry and peeling and there was a small crack at the left commissure.

By the 26th day, the patient was practically well. The dermatitis, stomatitis, diarrhea, psychosis and tachycardia had all cleared. On close questioning it was found that during the 6 weeks between the time she was first informed that she would probably have to have an operation and its actual performance she had been so worried about the operation and its attendant risks and discomforts that she had eaten poorly.

This thin, anxious, forty-seven-year-old woman developed classic pellagra with diarrhea, dermatitis, stomatitis, psychotic manifestations and tachycardia during an afebrile postoperative course as the result of poor eating habits for six weeks prior to operation and practical starvation for the first

week after it, the deficiency of vitamin B being further accentuated by intravenous infusions of glucose solutions (cf. Cowgill's caloric vitamin B ratio¹). One may speculate whether the tachycardia was due to thiamin deficiency although it is only of academic interest, since the patient obviously suffered from a niacin deficiency and there was almost certainly an associated thiamin deficiency.

Incidentally, it is also possible that vitamin B deficiency may be a contributory factor in some cases of postoperative gastric dilatation, intestinal distention and ileus and impaired bladder function.

CASE 4. H. C., a 69-year-old woman physician, was a chronic alcoholic and morphine addict. She had had so-called "colitis" for 10 years and had been diagnosed as having pellagra 5 months before I first saw her. She had been giving herself parenteral injections of a preparation of vitamin B complex since the diagnosis of pellagra had been made, but had continued her morphine and alcohol habits. She was seen in consultation because of cardiac failure. She was found to be obese, to have pinpoint pupils, — the result of morphine, — a severe glossitis, scaling and discoloration of the skin of the lower legs and roughness of the skin on the backs of the hands. The skin of both thighs showed innumerable scars of hypodermic injections. The heart was fibrillating (rate, 120), the blood pressure was 125/100, and there were signs of congestive failure. There were no murmurs, but the examination of the heart was not satisfactory owing to poor co-operation. The liver was felt two fingerbreadths below the costal margin. The reflexes were equal and active, and there was no tenderness on firm pressure on the calves.

Diagnoses of obesity, cardiac failure, morphinism, alcoholism and mild pellagra were made. The patient was rapidly digitalized and the previous dose of parenteral vitamin B complex was trebled. Three days later, when the heart rate was well controlled, she became completely disoriented. The daily morphine allowance was reduced, but she became psychotic and developed an intractable diarrhea. Although diarrhea is accepted as a common manifestation of withdrawal of morphine, there seemed to be an equal possibility that vitamin B deficiency was a contributory factor, so that 100 mg. of nicotinic acid was given by mouth every 2 hours. Two days later the patient was mentally clear, but the loose stools continued.

This obese sixty-nine-year-old woman, who was addicted to alcohol and morphine, had both severe cardiac failure and relatively mild pellagra. With adequate digitalization and gradual withdrawal of morphine she became psychotic and had severe diarrhea. The suggestion is made that one or both of these symptoms were manifestations of the pellagra, perhaps accentuated by the rapid restoration of cardiac compensation. One wonders whether some of the so-called "digitalis toxic psychoses" that appear in chronically decompensated cardiac patients, usually coincident with or immediately following a rapid diuresis and clearing in a few days' time with improvement of the cardiovascular status and ability to eat, may not be largely due to vitamin B deficiency.

Cowgill¹¹ showed that in dogs a diuresis produced by feeding large amounts of water by stomach tube hastens the time of onset of the anorexia characteristic of a deficiency of the vitamin B complex. His explanation is that significant amounts of vitamin B are carried off in the increased urinary output.

If the concentration of vitamin B in edema fluid is significantly less than that in the circulating blood, a diuresis produced by digitalis or mercurial diuretics might well be expected to hasten the development of clinically apparent vitamin B deficiency.

CASE 5. S. C., a 57-year-old man, was seen at home complaining of pains in the legs and back and diarrhea of 2 months' duration. One year previously he had had intestinal obstruction, and at operation a carcinoma of the colon was found. The entire right colon was resected. He gained strength and felt extremely well for the next 10 months, but intestinal obstruction recurred and a second operation revealed extensive intra-abdominal and intrahepatic metastases. A short-circuiting operation was performed, but the patient had had diarrhea steadily ever since. He had also had considerable pain in the right lower quadrant of the abdomen and had taken a great deal of codeine in an attempt to control it. He had recently shifted to morphine by mouth but was still having three to five stools a day and considerable aching in the legs and back. X-ray films taken the preceding week had shown no changes in the spine, pelvis or femur. He had lost about 25 pounds in the preceding 2 months, but still weighed about 200 pounds.

Physical examination showed a well-developed and fairly well-nourished man who gave evidence of recent weight loss. The tongue and mouth were normal. There were multiple hard masses throughout the abdomen, and the liver was felt at the level of the umbilicus.

A week later, in addition to having diarrhea, the patient began to vomit two or three times a day. Two weeks after the first examination the tongue was noted to be fiery red and dry. The vomiting and diarrhea continued. Three days later the mouth became sore, and a week later it showed many shallow ulcerations. No attempt was made to give parenteral nicotinic acid, thiamin or vitamin B complex. It was impossible to determine how much of the pain was due to neuritis secondary to the vitamin B deficiency or how much to the known extensive carcinoma. Cure was impossible, so that only palliation was attempted in the last weeks of life.

This fifty-seven-year-old man, who had extensive metastatic carcinoma of the liver and peritoneal cavity, a short-circuiting bowel operation and diarrhea of two months' duration, developed pellagra in the last two weeks of life. Profound malnutrition from chronic diarrhea, vomiting and extensive metastases in the liver were contributory factors.

CASE 6. A. F. M., a 72-year-old woman, was seen in 1936 because of an extremely sore tongue of at least 5 years' duration. Three years previously she had been minutely studied in a teaching hospital because of the same complaint. Most of the time she was overweight, spoon-shaped fingernails and a smoky, shiny, red painful tongue were noted. Blood studies ruled out both pernicious anemia and hypochromic anemia, and no clue to the painful glossitis was discovered. All the time she had been extracted some years previously, and double dentures had been worn ever since.

In 1936 the tongue still looked the same as it had in 1933, with the exception that there were some small superficial ulcerations at its tip. With the findings of Blankenhorn¹² in mind, a diagnosis of glossitis from vitamin B deficiency was made. A careful dietary history revealed marked meat deficiency since the teeth had been extracted and a partiality for white bread.

During the next 2 years, tablets of brewer's yeast, nicotinic acid and riboflavin were administered in large amounts with no apparent effect except a mild psychologic improvement. Finally, because of obvious failure to influence the patient's affliction therapeutic attempts were abandoned for 4 years. In 1942, the patient began to lose weight at an alarming rate. There were few symptoms except the earlier on sore tongue, increasing difficulty with vision owing to cataracts, shortness of breath, and general weakness attrib-

teriosclerotic heart disease. Extensive x-ray studies had no evidence of organic disease other than arteriosclerosis. The patient's own physician finally decided to try intramuscular injections of liver. The result was miraculously. From the date of the first injection she began to improve. The first symptom to disappear was the sore tongue, which had been present almost continuously for 11 years. She next developed a ravenous appetite. In the next 6 months she gained 20 pounds, and although she had been expected to survive the winter, she became strong and well.

This elderly woman with double dentures had had painful glossitis for eleven years that failed to respond to yeast, nicotinic acid and riboflavin by mouth but improved miraculously after injections of liver extract. Apparently the glossitis was of the type seen in sprue and pernicious anemia, which, as shown by Castle and his co-workers,¹³ responds to liver extract orally or parenterally but not to orally administered components of the vitamin B group. Of considerable theoretical interest is the fact that even after eleven years the glossitis was still a reversible process and was completely relieved by the intramuscular injection of liver extract.

It seems not unlikely that a certain number of the symptoms usually associated with advanced age — mental confusion, loss of memory, disorientation at night, mildly paranoid ideas, asthenia, loss of appetite, weight loss and neuritis or rheumatic pains — are partially caused by vitamin B deficiency and not, as is usually assumed, solely by cerebral arteriosclerosis.

CASE 7. H. D., a 38-year-old farmer and shipyard worker, with an unusually strong frame and a tremendous capacity for hard manual labor, had had pains in the forearms and hands for about 6 months, and cramps in the forearms sometimes kept him awake at night. Every morning it took him some time to limber up his fingers. Milking became extremely painful and using a hammer for more than an hour, as in shingling or caulking, became an impossibility. The hands and arms had never been frozen and the patient had not been exposed to lead paint or lead fumes for any period of time; he took alcohol only on rare occasions.

Physical examination showed a robust, red-checked, extremely healthy-looking man weighing about 200 pounds. He carried 10 to 20 pounds of extra fat. The tongue was entirely normal, and the rest of the examination was negative. There was no demonstrable weakness of the muscles of the hands or forearms, and all the reflexes were normal.

Questioning as to diet revealed a special liking for potatoes, of which the patient ate six or eight a day, and white bread and a distaste for meat. His daily schedule involved getting up at 6 a.m., doing the milking and farm chores, working at a shipyard from 8 a.m. to 4 p.m., resuming his farm work, delivering milk and getting to bed between 11 p.m. and midnight.

On the remote chance that the pains were due to neuritis arising from a relative vitamin B deficiency caused by the enormous total metabolism, high-starch diet and low intake of vitamin B, 9 capsules of vitamin B complex were given daily by mouth and the patient was advised to take less potatoes and white bread. In 6 months the paresthesias had disappeared and the patient regained full use of his hands and arms.

This extremely vigorous, active, overweight farmer and shipyard worker, who averaged fourteen to eighteen hours of physical labor daily, developed a severe neuritis of both forearms and hands interfering seriously with his work. His diet was high in

calories and starch and relatively low in foods containing vitamin B. His neuritis cleared up when his diet was corrected and supplements of vitamin B were added.

Obesity was possibly a minor contributory factor to the dietary deficiency in this case. It may contribute to vitamin B deficiency because it is always associated with an increase in total metabolism (Newburgh¹⁴), and because the more obese a person is the more likely his caloric vitamin B ratio (Cowgill¹⁵) to be deficient. Adiposis dolorosa (Dercum's disease¹⁶⁻¹⁸), with its asthenia, neuritis and psychosis, sounds suspiciously like an extreme example of obesity predisposing to vitamin B deficiency.

CASE 8. E. G., a 22-year-old stenographer, was seen with typical scarlet fever on the 3rd day of her illness. It had begun as an extremely sore throat. The patient had had great difficulty swallowing even fluids. The temperature was 105°F. and the pulse 130. The throat showed extensive exudate on both tonsils, and the right tonsil was pushed forward. There was a typical scarlatiniform eruption. The heart had no murmurs, and there was no history of rheumatic fever, chorea or a previous peritonsillar abscess.

The patient was hospitalized the next morning and was given antitoxin and sulfamerazine because she was extremely toxic. One day after admission the blood sulfamerazine level was zero, probably owing to an accidental confusion of blood samples, so that the drug was continued in full doses. The next day the level was 29 mg. per 100 cc. and the patient had oliguria. The drug was stopped and she was given glucose and saline infusions. Four days later the temperature fell to 100°F. Large quantities of urine were being excreted, but the patient had paranoid ideas, a gallop rhythm and what some observers called a pericardial friction rub but which I interpreted as a contact sound. At that time she looked a great deal better than she had when first seen 6 days before. The throat was much less sore, and she was able to swallow without much discomfort. The right tonsil was still pushed forward. There was fissuring at the outer corners of the eyes and lips. The tongue was smooth and red, with occasional enlarged papillas protruding above the surface. The heart was rapid and regular at a rate of 120/140, and the temperature was still 100°F. There was a well-marked gallop rhythm, and the above-mentioned scratchy sound was synchronous with both the 1st and 2nd sounds at the lower end of the sternum.

On the basis of paranoid ideas, cheilosis and embryocardia with gallop rhythm, a diagnosis of acute vitamin B deficiency was made. The contributory factors were sepsis, fever, inability to eat solid food for 8 days and intravenous infusions of glucose solution. A cardiac consultant made a diagnosis of acute rheumatic myocarditis and pericarditis, and the visiting physician a diagnosis of scarlet-fever heart.

The patient improved rapidly from this time on, having begun to eat well. The next day, she became and remained mentally clear, the heart began to slow down, and the friction rub disappeared almost at once.

Fifteen days after the onset of scarlet fever a peritonsillar abscess on the right ruptured spontaneously. At that time there were also migratory transient joint pains, with slight redness and limitation of motion for a few days. The electrocardiogram never showed a PR interval greater than 0.18 second, and all tracings showed a tendency to slight right-axis deviation. A soft apical systolic murmur developed, and the sedimentation rate was two or three times normal.

From the 17th day of the illness there were no further joint pains, fever or any other symptoms. The convalescence was uninterrupted. The sedimentation rate finally became normal 2 months after the first symptoms. When the patient was last seen, 10 weeks after the onset of the scarlet fever, the examination of the heart was entirely normal except for a faint apical systolic murmur, which was heard only when she was lying down and disappeared on exercise.

This healthy young woman with no previous history of rheumatic fever or any other type of heart disease developed paranoid ideas, cheilosis and tachycardia with gallop rhythm eight days after the onset of severe scarlet fever. The acute vitamin B deficiency was precipitated by fever, sepsis, inability to eat and intravenous infusions of glucose solution. It is impossible to establish an exact diagnosis of the cardiac lesion. Unfortunately, there are no pathognomonic signs or laboratory tests for differentiating or diagnosing some cases of rheumatic myocarditis, beriberi heart and scarlet-fever heart.

Wesselhoeft,¹⁹ from his extensive experience with scarlet fever, describes scarlet-fever heart as a transient affair lasting for a few days to three weeks. It usually consists in the development of murmurs, without irregularity in rhythm. The first sign is generally a split first sound. Abnormalities are likely to be noticed when the patient is first allowed out of bed. The murmur is extremely variable in time and character. It may occur in systole or diastole, but more frequently in the former. Some writers have emphasized that its occasional harshness is somewhat suggestive of a slight friction rub at the base. The heart rate is not necessarily increased with the advent of these abnormal sounds, but quite independently of them there may occur a persistent tachycardia or even a relative bradycardia. There is rarely any cardiac enlargement, and there is no precordial pain or discomfort. All these clinical signs usually disappear by the end of a week, and in marked cases in three or four weeks. Electrocardiographic changes are variable, inconstant and nonspecific.

A similarity may be seen in this description between scarlet-fever heart and the milder forms of beriberi heart disease (Weiss and Wilkins⁹). There are no clinical or laboratory tests that distinguish between them with certainty. The suggestion is made that they may be identical conditions. The excellent prognosis of practically all cases of scarlet-fever heart may be explained by the fact that once the acute sore throat of scarlet fever subsides the patient begins to eat. Also, the normal nutritional status of most persons preceding an attack of scarlet fever renders them less likely to develop the more advanced stages of beriberi heart disease.

CONCLUSIONS

The above 8 cases of clinical vitamin B deficiency were seen in seven years of private practice. They have been reported in the hope of emphasizing the frequency with which this group of diseases occurs as a complication of many serious illnesses seen every day in practice. Therapy is self-evident if

the diagnosis is made. An acute awareness of the existence of such conditions is necessary if the cases are to be correctly diagnosed and treated their earlier stages.

The precipitating or contributory factors in the small series were fever, a bizarre diet, chronic diarrhea, poor teeth or poorly fitting dentures, operative apprehension, infusions of glucose solution, hard manual labor, obesity, drug addict diets rich in starch and sore throat or sore mouth. In any given case there was usually more than one factor.

It may be repeated that symptoms of vitamin B deficiency may develop whenever an elevated metabolism occurs simultaneously with a deficiency of vitamin B-containing substances in the diet or any interference with absorption in the gastrointestinal tract. These should be looked for in cases of fever, increased caloric intake, increased muscular activity, hyperthyroidism, chronic diarrhea or vomiting and the like, with or without obvious limitation of intake or absorption of vitamin B-containing foods.

THE PURPOSE AND ACCOMPLISHMENTS OF THE LAWRENCE CLINIC

H. FRANK MCCARTHY, M.D.,* AND FREDRICK C. ATKINSON, M.D.†

LAWRENCE, MASSACHUSETTS

1936, one of us (H.F.M.) became convinced, through observations made during the course of practice, that there should be in Lawrence an institution devoted primarily to the care of the socially indigent. It was noted that because of the lack of adequate outpatient facilities, poor patients were prone to employ a physician or surgeon until accumulated bills became prohibitive, and then, because of inability to pay the incurred debt, "passed" from physician to physician. Because of numerous experiences of this sort, it was obvious that there was an urgent need for this charitable institution. Accordingly, the interest of the late W. Dacre Walker, a physician of influence and high repute in this community, was enlisted, and after considerable study and thought he gave the subject his wholehearted support. Dr. Walker became the first president of the Board of Trustees and the first chief of staff.

On November 13, 1936, the charter was granted and a group of outstanding lay persons consented to act as trustees. A meeting was held by nine representative physicians and dentists of the community and plans to open a free outpatient clinic were formulated. Aided by funds and equipment donated by these physicians and dentists, on January 6, 1937, the clinic made its inauspicious start, poorly housed in a somewhat dilapidated local building. A certain amount of criticism, which is usually attendant on an innovation, was at first directed toward the clinic, owing to the mistaken impression that its primary purpose was the financial gain of its sponsors. Criticism abated and suspicions were allayed once the public became convinced of the worthiness and sincerity of the project.

It was early recognized that the services of the clinic would be sought by many who could afford private care. Accordingly, rigid rules for admission were devised. It was decided that candidates for the clinic should be admitted only on the presentation of a reference from a physician, dentist, minister or recognized charitable agency, stating that the bearer could not afford to pay for private care. In a few cases it was found that the referrer had recommended patients who were not financially deserving of clinic care. They were warned, and if the offense was repeated their privilege to refer patients was revoked. Again, on a few occasions it was found that physicians referred patients for special work, such as laboratory or x-ray examination, who were not eligible, but when it was explained to them

that patients must also be of clinical status to receive this care, the difficulty was eliminated.

SOCIAL RELATIONS

The case load in the early days of the clinic was extremely heavy because of conditions in the mills following the Depression. Recently, with the advent of war production, the load has dropped considerably and, for the first time in many years, people who were formerly on the relief rolls and had received free care at the clinic have become contributors to its support. This point is important, since in a community of the type of Lawrence the borderline between prosperity and poverty is frequently the holding of a job. In the files of the clinic are hundreds of letters of gratitude written by former patients who wish it to be recognized that they have now assumed the role of givers rather than receivers.

The clinic is at present maintained by public donations, which are solicited by mail. About \$10,000 is received yearly from approximately 3000 donors. There are a few large annual donations made from several organizations, but it is apparent from these figures that the bulk of the money received is in small amounts and is sent from a cross section of the working people of the community. A survey of the list of donors is convincing proof that the clinic is being largely supported by potential patients, and a great many of their letters indicate that they are cognizant of this fact.

STAFF

The original charter members interested other members of the medical profession in the project. These physicians and dentists staffed the various departments and have given generously of their time year after year, with no remuneration other than the gratitude of the patients. Many of the original staff were young men, not too busy in their private practice and not at the time affiliated with any other local institution, so that they could afford to spend considerable time when the medical case studies were to their professional advantage. For the cases that require special study, ten outstanding Boston specialists act as consultants to the various departments, and the clinic has been accorded the privilege of referring to them such patients as require their attention. These men, also, have worked without financial remuneration.

As in other instances, the war has brought special problems to this institution. As stated above, the clinic was originally staffed almost wholly by youthful physicians and dentists. Now that the various

*Chief-of-staff, Lawrence Clinic.

†Head of Medical Department, Lawrence Clinic.

branches of the service have recruited most of them, out of the original staff of fifty-two only nine are now active at the clinic. These men, however, can adequately handle the work because of the lighter case load resulting from improved economic conditions.

ADMINISTRATION

The number of paid workers at the clinic is eight, consisting of a superintendent, a secretary-bookkeeper, a clerk, a laboratory technician, a medical assistant, a registered nurse, a dental hygienist and a janitor. These paid workers, however, are augmented by numerous volunteer workers in all departments from office work to medical assistance. Most of the administrative staff are underpaid in comparison to their efforts, but have stayed on in spite of opportunities for higher pay, feeling recompensed by the satisfaction that comes to those who render a community service. Through the kindness of a prominent local accountant, a bookkeeping system was installed, and this is audited yearly without charge.

FACILITIES

In April, 1940, after three years of operation in humble surroundings, the clinic moved to its present location. Under the supervision of the Board of Trustees, the building in which it is now housed was purchased, and although heavily mortgaged at the time of purchase, it was possible to renovate it completely and to equip each department with the most modern equipment. The rooms, which are clean and wholesome, are unpretentious and strictly utilitarian. Most of the available money was expended on good medical equipment rather than in beautifying the surroundings. This, in the opinion of the staff, was much more advantageous to the patients' welfare. All departments are well equipped, and they include a dental clinic with two chairs. Some of the departments are supported by various organizations, as in the case of the Eye, Ear, Nose and Throat Department, which is sponsored by the local Lions Club.

Medicine is dispensed free or at cost. In 75 per cent of the cases it is given without charge. Appliances such as arch supports, eyeglasses and back braces are obtained for patients at cost, but if the latter are unable to pay even this amount, an endeavor is made to procure the appliances through some welfare organization. As a last resort, the clinic will purchase such appliances for a worthy patient.

When a patient needs hospitalization for surgery, efforts are made to secure a free bed in a private hospital, and the clinic's staff surgeons do the operating without charge. In certain cases patients are referred to the municipal hospital.

Among other facilities available to patients: completely equipped x-ray department. Here the patient if financially able pays the exact amount of the material used. If he is unable to pay, work is done free. The clinic has a well-equipped laboratory with a competent technician in charge.

In June, 1938, a state venereal-disease clinic was assigned to the Lawrence Clinic. Needless to say, this is always one of the busiest departments. The State reimburses the clinic on a per capita basis for each patient treated, and although no results from this arrangement, it makes this particular department self-supporting.

On first admission, a patient is requested to pay an admittance fee of 50 cents, and 25 cents for each successive visit. The admission fee was decided upon as a morale factor and for its psychological effect on the patient rather than for the financial return expected from it. About 65 per cent of the patients are unable to pay even this small fee and are admitted free. Their ability to pay or to receive free care is determined on the first admission by the admitting clerk. The economic status of each patient is watched as carefully as possible, and improvement in such status, the patient is urged to return to his family physician for medical care when he again becomes eligible for clinic care.

LADIES' AUXILIARY

Shortly after the opening of the clinic, civic-minded women volunteered their services to the institution in various ways. They often drove elderly patients to and from their homes, made medical supplies, sewed curtains and in many other ways assisted in the undertaking. This group was the nucleus of a larger group of women who formed the Ladies' Auxiliary. This auxiliary has been invaluable to the clinic. Its members have sponsored benefit parties and have raised considerable sums of money. They have been to a great extent a factor in promulgating goodwill throughout the community and in helping to dissipate any latent suspicions that might still be entertained regarding the purpose of the institution.

* * *

The clinic is about to enter on its seventh year of service to the medically indigent of Lawrence and the surrounding communities. During the past years approximately 100,000 treatments have been received by these people. If it is borne in mind that all the patients have been bona-fide charity patients it will be realized that the institution has justified its existence and established its position as a social necessity. If in this period only a few human beings had been rehabilitated, — and there have been hundreds, — the sponsors of the clinic would still find that the end had been worth the means.

MEDICAL PROGRESS

PIGMENTATION OF THE SKIN (Concluded)*

HAROLD JEGHERS, M.D.†

BOSTON

MELANOSIS ASSOCIATED WITH AN INCREASED NUMBER OF MELANOBLASTS

BECKER and Obermayer¹⁰² classify a number of pigmentary disturbances as melanosis associated with an increased number of melanoblasts (Table 2). Some of these are of general medical interest. The increased melanoblasts of the blue nevus (see colored plate³⁰⁵) and of Mongolian spots (see colored plate²⁸) are deep in the corium, so that the resulting melanin pigmentation appears blue. Blue nevi bear the same relation to Mongolian spots as the ordinary brown moles do to brown-pigmented skin.³⁰⁶ Mongolian spots are frequently noted over sacral and other areas in the darker races and occasionally in the white-skinned races, and persist for a variable number of years after birth.³⁷

Ephelides (freckles)^{11, 22, 102, 103} are due to increased aggregates of melanoblasts producing accentuated, sharply demarcated yellowish-brown areas, often zizzag in outline. They are more obvious in spring and summer, can be seen with Wood's light when invisible to the naked eye (see illustration³⁰⁷), appear early in life but not in infancy, never occur on the palms and soles and are prominent on the exposed parts of the body, and the predisposition to them is an inherited dominant characteristic. They may be confused with lentigo and melanosis produced by disease.

Melanotic neoplasms of the skin are frequently encountered. The difficulty of treating them and the frequency of metastasis from them are well known. Of significance here is the observation that aside from true metastases, malignant melanoma may cause a diffuse and marked melanin pigmentation of the skin.³⁰⁸⁻³¹⁰ In a reported case (see illustration³⁰⁸) a white man became so dark in color that he was thought to be a Negro.

Sharply outlined brown blotches, *café au lait* spots and large areas of brown skin pigmentation (see illustrations^{311, 312}) are among the commonest features of neurofibromatosis (Recklinghausen's disease), and in some reported series were noted in every patient.^{311, 313} The pigmented spots are usually not congenital and may develop in childhood or later in life. The pigmentation in this disorder is considered to be due to a localized anatomic anomaly

in the cutaneous nerve itself that produces the increase of melanin in the epidermis.³¹³ In its classic form neurofibromatosis is readily recognized. It is, however, not well appreciated that in the formes frustes^{312, 313} pigmented spots on the skin may be the only visible manifestation of the disorder. It is now well known that neurofibromatosis may involve many internal organs, including the bone, the central nervous system, and the endocrine organs, and it is therefore of general medical interest.^{312, 314} The possibility of neurofibromatosis should not be overlooked in persons with patches of brown skin pigmentation of this type.

Much interest has been aroused in recent years in a curious syndrome characterized by osteitis fibrosa disseminata, areas of pigmentation and a gonadal dysfunction, especially precocious puberty in the female.^{315, 316} It has been referred to in the recent literature as osteitis fibrosa cystica (Albright) and Albright's syndrome. The disorder is not due to parathyroid disease. The patchy skin pigmentation seen in this disorder is almost constantly present, is brown in color with no change in skin texture, is due to melanin, and on histologic examination is similar to the pigmentary lesion of neurofibromatosis (see illustrations³¹⁵). The skin pigment is often distributed in the same general area of the body as that in which the cystic bones are located. Its occurrence in children, the pigmented areas and endocrine stigmas, lack of generalized decalcification and normal blood calcium and phosphorus values serve to distinguish this disorder from hyperparathyroidism with osteitis fibrosa cystica generalisata. Thannhauser³¹³ has recently suggested, citing much evidence in support of his belief, that the pathogenesis of neurofibromatosis and that of osteitis fibrosa cystica localisata and disseminata are related. He refers to them as neurofibromatosis (Recklinghausen) and osteitis fibrosa cystica localisata et disseminata (Recklinghausen). The many similarities of the pigmentary syndromes of both conditions are strikingly emphasized in his paper.

Leschke's syndrome,³¹⁷ the association of the pigmentary syndrome of neurofibromatosis with an endocrine syndrome, is probably only a variant of neurofibromatosis. It has been especially emphasized in the German literature (see illustration³¹⁸).

The association of skin melanomatosis with melanomatosis of the central nervous system, aside from the possibility of a skin melanoma metastasizing there, has been reported^{319, 320} and is considered

*From the Evans Memorial, Massachusetts Memorial Hospitals; the Fifth and Sixth (Boston University) Medical Services, Boston City Hospital; and the Department of Medicine, Boston University School of Medicine.

†Associate professor of medicine, Boston University School of Medicine; physician-in-chief, Fifth Medical Service, Boston City Hospital, and assistant physician, Clinical Staff, Evans Memorial, Massachusetts Memorial Hospitals.

a congenital neurocutaneous syndrome and grouped with tuberous sclerosis of Bourneville and Brissand, neurofibromatosis and hemangiomas of the meninges associated with similar nevi of the skin. The pigmented spot that occasionally occurs on the back over the site of a spina bifida occulta probably also belongs in this group of pigmentation due to increased melanoblasts.

HEMOGLOBIN PIGMENTATIONS

Variations in skin color produced by changes in the amount or nature of the hemoglobin contained in the capillaries and subpapillary plexuses of the skin are far more frequent in medical practice than are the types due to deposition of an exogenous or endogenous pigment in the tissues of the skin. This review does not cover them in any detail, but the more important ones will be mentioned so that the wide range of possible skin color change will not be overlooked.

Environmental and emotional control of skin capillaries may cause a red-flushed, a pale or a cyanotic skin. Pallor due to anemia, the reddish-blue facies of polycythemia vera (see colored plate³²¹), the cherry-red color of carboxyhemoglobinemia (see colored plate³²²), the bright red color of nitric oxide-hemoglobinemia which may result from poisoning by fumes from combustion of explosives, the chocolate-blue color of methemoglobinemia (see colored illustration³²³) and the lead or mauve-blue color of sulfhemoglobinemia are striking and contrasting examples. The color of cyanosis due to increased reduced hemoglobin may vary from the deep purplish blue (see colored plate³²⁴) of strangulation to the heliotrope cyanosis (see colored plate³²⁵) noted in certain types of pneumonia. Lewis's³ colored plates for the study of cyanosis illustrate the many tones and hues that the skin color may manifest in this condition. A predominance of oxyhemoglobin in the skin color accounts for the redness of such conditions as the flushed face of alcoholism, the emotional blush, erythemas and inflammatory lesions. Hydrocyanic acid combines poorly with hemoglobin or oxyhemoglobin, but combines readily with methemoglobin to form cyanhemoglobin, which differs from ordinary hemoglobin in its bright-red color. This compound is responsible for the bright ecchymotic spots often seen in the skin of patients who have died from hydrocyanic poisoning.³²⁶ Pronounced melanin pigmentation of the skin may serve to screen out influence on skin color due to hemoglobin variations, — that is, in Negroes, — but this is not generally so marked for mucous membranes.

METALLIC PIGMENTATIONS OF THE SKIN

Hemosiderosis

"Hemosiderin" is the name applied to an iron-containing pigment that mainly occurs in the body

as a result of local or general destruction of blood and in hemochromatosis. "Hemosiderosis" is a general term used to designate the process characterized by deposition of hemosiderin pigment in the superficial corium, with resultant pigmentation. How much of the pigmentation can be directly attributed to hemosiderin deposition alone and how much to melanin production initiated through local action or through deposition of hemosiderin in the adrenal glands is not entirely clear. In some forms of hemosiderosis an accompanying melanin pigmentation — that is, hemochromatosis — is common. Hemochromatosis and a variety of hemologic disorders are the main systemic causes of hemosiderin formation. The most frequent type, however, occur on the lower legs because of a variety of combinations of local and systemic disturbance.

Hemochromatosis. Pigmentation of the skin is one of the most constant and characteristic features of hemochromatosis. Butt and Wilder³²⁷ noted its absence in only 1 of 30 cases studied by them. Case reports stressing the rarity of its absence attest to the almost constant presence of the pigmentation.^{328, 329} This may appear late in the disease, but it is often present for years and is frequently the first symptom to attract attention.³³⁰

A detailed discussion of skin pigmentation is given by Sheldon³³⁰ and Hellier.³³¹ Hemofuscin, an iron-free pigment, although usually present in hemochromatosis is not highly important in causing skin pigmentation. Melanin and hemosiderin are the two pigments concerned with the changes in color of the skin. Hemosiderin is found chiefly in the corium, mainly in the neighborhood of the sweat glands, and perhaps to some degree in the deeper epidermis.³³⁰ It is at times solely responsible for pigmentation of a bluish-black, slate or lead color, which is sometimes generalized but is always more marked on the face, the neck, the extensor surfaces of the limbs and usually the external genitalia.^{330, 331} Melanin is found in the deepest layers of epidermis and occasionally to a small degree in the chromatophores of the corium. Alone, it causes the usual brownish type of pigmentation characteristic of melanin pigmentation.

It appears from case reports that melanin tends to be the earlier type of pigmentation. This is suggested by the almost constant presence of hemosiderin in the skin in autopsy reports, whereas many biopsy studies of the pigmented skin at earlier stages reveal no hemosiderin. When both pigments are present, melanin modifies the color and blends the slate gray of hemosiderin with brown to give a bronzed appearance³³¹ (see colored plates³³²⁻³³⁵).

Hellier³³¹ records the findings of the skin histology of 57 cases from the literature and his own as follows: hemosiderin was present in 48 cases, absent in 5, and not mentioned in 4; melanin was present in 35 cases, absent in 12, and not mentioned in 10.

cases hemosiderin was present without melanin; these patients had a slate-gray or bluish color. It is evident that melanin pigmentation is far more frequent and contributes more to the skin color than is generally appreciated. The classic bronze color depends on this frequent combination of the two pigments. The early appearance in the skin of melanin pigmentation alone suggests that the mechanism is related either to hemosiderin deposition in the adrenal glands or perhaps to cortical function of some other nature.^{330, 331}

In Sheldon's³³⁰ extensive review the mucous membranes were reported as pigmented in 16.7 per cent of the cases studied — usually in the mouth and next most frequently in the conjunctivas. The pigment is apparently of the melanin type, although one report of the demonstration of hemosiderin was given.

The intensity of the pigmentation has been reported as occasionally increasing noticeably shortly before death,³³⁰ and also as diminishing rapidly when the diabetes accompanying the disorder is controlled with insulin.³³⁶ This is usually attributed to a metabolic change within the skin cells that alters its optical character rather than to dissolution or removal of the pigment.³³⁰

Skin biopsy in hemochromatosis is often poorly handled for the best results. The pigments are diffusely deposited in the skin over the entire body. One should avoid taking the skin from the legs, over pressure areas or irritated areas or from a body fold. Hemorrhagic disorders and blood dyscrasias as causes of hemosiderin formation must be excluded by appropriate hematologic studies. A request should be made for the study of melanin pigmentation as well as of stains for the iron-pigment fraction. Other aids to the diagnosis of hemochromatosis are Rous's test of the urine sediment,³³⁷ examination of sediment from ascitic fluid for iron pigment,³³⁸ the presence of insulin-resistant diabetes³³⁹ or, for that matter, any degree of diabetes in a pigmented patient or diabetes with an elevated basal metabolic rate, pigmentation in a patient with ascites, cirrhosis or an enlarged liver, Fishback's skin test³⁴⁰ and evidence of sexual hypoplasia.³⁴¹

Hemosiderosis of the lower legs. Hemosiderosis of the lower legs with skin pigmentation is frequently encountered in both general and dermatologic practice. Either gross or microscopic extravasation of red cells into the skin for long periods of time leads to deposition of hemosiderin pigment in the corium and gradually to pigmentation of the skin, usually a brownish, sepia or copper hue. It may be fairly diffuse or centered about ulcers of all types. It is oftenest seen with the stasis of varicose veins but is not uncommon in patients with other types of stasis, for example, chronic ascites.

Inflammatory and other stimulants for melanin formation are also present. Patients with this type

of leg pigmentation who have glycosuria, an enlarged liver, cirrhosis, ascites and so forth are often erroneously suspected of having hemochromatosis and a biopsy specimen of skin is taken from the pigmented area, the report of which leads to more confusion.

Supporting pressure on the tissues from shoes tends to protect the feet from the hemosiderosis. It is likely to commence near the ankle, to extend a variable distance toward the knee and to be more prominent anteriorly than posteriorly. Any hemorrhagic disorder if chronic, increased fragility of capillaries, diminished tissue elasticity of old age and so forth, if added to venous stasis, may accentuate the development of the process.

Of general medical interest is the occurrence of this type of skin pigmentation as a sequela of repeated mild trauma to the lower legs, in stasis from varicosities and probably other causes, in hemochromatosis (here diffuse over the body and not limited to the legs); about the leg ulcers in sickle-cell anemia,¹⁷⁴ congenital hemolytic jaundice,^{171, 172} in Cushing's disease,³⁷⁰ Gaucher's disease,¹⁸⁵ in perniosis,³⁴² and probably in other conditions. The occurrence of pigmentation on the lower legs, especially in a young person without varicose veins, may be a clinical finding of some significance. Of dermatologic interest are Schamberg's disease^{343, 344} (see colored plate³⁴⁵), Majocchi's disease³⁴⁴ and others.^{343, 346, 347} These disorders are listed in Table 3.

Argyria

Argyria is the pigmentation resulting from deposition of silver in the corium of the skin and mucous membranes. The monograph on argyria by

TABLE 3. *Causes of Hemosiderosis of the Lower Legs.*

Sickle-cell anemia*	

*Included in this tabulation on circumstantial evidence. The nature of the pigmentation is not clearly stated in the available literature.

Hill and Pillsbury³⁴⁸ based on over six hundred references attests to the world-wide interest in this subject. Any silver compound is capable of producing argyria when used for a sufficiently long period of time by any route of administration other than the intact skin. Argyria may result from the therapeutic use of silver as well as industrial exposure to it.³⁴⁹ The incidence of the condition appears to be increasing.^{348, 350} Silver is accumulated in the body over many years, and argyria develops when a sufficient amount has been deposited in the skin. The last silver preparation used before the

appearance of argyria is often erroneously blamed; if not sufficiently large in itself, it was only the amount that, added to previously stored silver, allowed the visual threshold to be reached. Silver can be demonstrated quantitatively in the skin by spectroscopic examination long before it is clinically observable.

Argyria is permanent and, other than the cosmetic disfiguration, has no effect on health. No adequate method of treatment is available, but small areas may be partially bleached.³⁵¹ Silver is deposited uniformly over all skin and mucous membrane surfaces in the corium but not in the epithelium. The areas of the body exposed to sunlight become strikingly accentuated, and such exposure should be strictly avoided by those with argyria of even minimal degree. Histologic diagnosis can readily be made from a skin biopsy.³⁵²

Argyria is clinically most pronounced on the face, hands, conjunctivas and fingernails. Because of pigment deposition in the corium, the color of argyria is usually described as slate gray, blue gray or lead, or in other words a blue varying from gray to blue (see colored illustration³⁴⁹). The ability of the pigmentation to simulate cyanosis is striking.^{348, 349} Levine and Smith³⁵³ recently reported 5 cases of argyria erroneously treated for cardiac disease because the argyria pigmentation had been mistaken for cyanosis. This has occurred in 3 patients studied at the Boston City Hospital. If the pigmentation is predominantly of a lead rather than a blue hue, the condition may be confused with melanosis or hemochromatosis.

Chrysiasis

Schmidt^{354, 355} has presented a valuable review of chrysiasis. He defines it as "a permanent pigmentation of the skin caused by the parenteral use of a gold preparation and the subsequent exposure of the skin to ultraviolet radiation, including sunlight." This potential hazard should be known to all physicians using gold. Chrysiasis is not uncommon after its excessive use.³⁵⁴ A latent period of one month to five years may elapse before the skin pigmentation makes its appearance; it then persists permanently. Lorenzen's³⁵⁴ study showed that "no patient receiving a total dose of less than 50 mg. of gold sodium thiosulfate per kilogram of body weight had definite chrysiasis and that no patient escaped having the condition if the total dose received was 150 mg. per kilogram of body weight." Cases in the earlier literature were noted after the gold therapy of tuberculosis, but gold therapy has been extensively used in arthritis in recent years, apparently without causing chrysiasis.³⁵⁶ The disease may appear only after a long latent period, so that a long follow-up is needed for one to be certain on this point.

The involved skin has been described as uniformly gray, slate gray, grayish purple, grayish blue,

bluish violet, blue green and brownish yellow. Chrysiasis appears after exposure to sunlight and is usually limited to the exposed portions of the body — the face, neck, arms, hands and sclera. The mucosa of the mouth is usually not stained. Predominant deposition in the upper corium accounts for the characteristic gray to blue hue of the skin pigmentation. Diagnosis can be made from dark-field study of histologic sections.^{348, 357} Treatment is not successful. Prophylaxis depends on minimal dosage of gold salts and avoidance of undue exposure to sunlight or ultraviolet radiation.

Bismuthia

The prolonged oral use of bismuth has been reported as rarely producing a generalized persistent skin discoloration (see colored plate³⁵⁸) resembling argyria that has been called "bismuthia." The conjunctivas and oral mucosa are pigmented. Bismuth is identified by chemical examination. The pigment granules are seen on histologic study to be evenly scattered through the corium. The rarity of this condition in spite of the common use of bismuth is worthy of emphasis. The factors essential for its production are not known. A black line of bismuth sulfide along the gums near the teeth is frequently seen in persons treated with bismuth. Tartar deposits on the teeth accentuate its formation. Pigmentation of the tongue and buccal mucosa is a warning symptom of impending stomatitis and nephritis.³⁶⁰

Wiener³⁶⁰ reported a case of bismuth pigmentation of the entire vagina in a syphilitic woman with ulcerative cervical cancer who had received bismuth therapy. This clinical syndrome appears at first glance to be analogous to the bismuth pigmentation of the gums, but may be more complex. Sulman et al.³⁶¹ treated 122 female albino rats with daily injections of bismuth and estrogenic or gonadotropic hormone preparations. Thirty to 80 per cent of the animals showed bismuth pigmentation of the vagina, but 60 control female rats treated with bismuth alone showed no blackening of the vagina. The pigmentation was believed to have been conditioned by hyperemia of the vagina from the hormone therapy, together with some unknown factor causing selective fixation of bismuth in the vagina.

Hydrargyria

Face creams containing mercury or mercury and bismuth may produce a peculiar discoloration of the skin (a brownish, gray or slate color), usually of the face and neck and limited to the areas where the material is applied, with accentuation in skin folds (see illustration³⁶²). Biopsy material shows mercurial deposits in the epithelium and corium.³⁶²⁻³⁶⁴ This type of pigmentation is purely of local origin. Goeckermann³⁶⁴ has commented on the ease with which it has been confused with pigmentations of

emic origin. The differential diagnosis of facial pigmentations is given in detail by Hollander³⁶² and others.^{359, 365}

d Pigmentation

The deposition of lead as lead sulfide within the tissue of the gums about 1 mm. from the border of the teeth, producing the so-called "lead line" or "Burtonian line" is widely recognized as one of the characteristic but not constant signs of lead poisoning. Lead does not cause pigmentation of the skin. The ashen-lead color of the face and pallor of the lips noted in lead poisoning is believed to be due not only to anemia but in addition to a possible action of lead on the skin capillaries.^{366, 367}

e Pigmentation

A permanent tattoo type of brown pigmentation of the skin may result if ferrous sulfate or ferric chloride solution along with solution of lead or aluminum acetate is used on a vesicular or open skin lesion, allowing contact of the chemical with the dermum. Pigmentation is due to dyeing of the corium with basic ferric acetate. Other agents than acetate may likewise enable iron to fix itself permanently to the protein molecule.³⁶⁹⁻³⁷⁰ This type of pigmentation is purely of local origin. In contrast to hemosiderin, metallic iron does not cause pigmentation of the skin through systemic action.

MISCELLANEOUS PIGMENTATIONS

a Porphyria

Watson³⁷¹ in reviewing the clinical features of porphyria points out that pigmentation of the skin is not uncommon in this disorder but that the nature of the pigment has not yet been determined. In congenital porphyria, he adds, uroporphyrin has been identified in the epithelial cells, where it is undoubtedly responsible, at least in part, for the marked sensitivity to light, a phenomenon that is usually absent in the intermittent acute type. In the congenital form of porphyria the teeth may be stained pink (see colored plate³⁷²).

Pigmentation of the skin in the intermittent acute types of porphyria is much more prominent on the exposed surfaces than on others; it may be patchy or diffuse, but at times covers the entire body and is bronze. Watson³⁷³ has not noted pigmentation of the mouth or other mucous membranes, a point also made by Nesbitt.³⁷⁴ Vitiligo was noted in 1 patient,³⁷¹ an observation suggesting a disturbance of melanogenesis in the skin. Whether the responsible pigment is melanin is not known. Porphobilin, a red-brown pigment occurring in porphyria, somewhat similar to urobilin but not having porphyrin characteristics, may be related to the skin color.³⁷¹ It would be quite compatible with its physical characteristics to find deposits of it in the skin.³⁷¹ Turner and Obermayer³⁷⁵ report

a case of porphyria accompanied by epidermolysis bullosa, hypertrichosis and melanosis.

Methemalbuminemia

Fairley^{169, 170} has recently given a detailed account of the blood pigment methemalbumin, first described by him in 1934. The chocolate-brown color it gives to plasma and its absorption characteristic on spectral analysis are so similar to the effects of methemoglobin that they have in the past been readily confused. It is pointed out that both methemoglobin and sulfhemoglobin are essentially confined within the red cells and that the term "methemoglobincythemia" should replace "methemoglobinemia" and "sulfhemoglobincythemia" should replace "sulfhemoglobinemia." Methemalbumin, on the other hand, is found only in the plasma. Hematin cannot exist as such in the circulating blood, and when formed combines with serum albumin to form methemalbumin. Methemalbumin is responsible for the brown color of plasma in blackwater fever and may be present in variable amounts in other hemolytic anemias. How much influence this pigment has clinically in causing changes in skin color is not clearly stated in the literature.

Malarial Pigmentation

Books on differential diagnosis commonly list chronic malaria among the disorders causing skin pigmentation. Some melanin pigmentation no doubt occurs, but the pigment problem in malaria is by no means simple. It is well known that the malarial pigment hematin is widely deposited in tissues, particularly in those of certain visceral organs. Furthermore, hemosiderin is formed.³⁷⁵ Jaundice occurs in some forms of malaria. Hemoglobinemia and methemalbuminemia occur in blackwater fever.^{169, 375} Strong's³⁷⁶ monograph on tropical medicine gives a detailed discussion of this complex subject.

Pigmentation Due to Other Medicinal Agents

Many colored chemicals, used either therapeutically or diagnostically or acting as poisons, often produce temporary skin discoloration. All physicians are familiar with some of these substances. Typical of this group are methylene blue, injectable Prontosil, Evans blue, Congo red, acriflavine, san-tonin, atabrine, dinitrophenol and many others.

Other Pigmentations

Vitiligo and gray hair. Vitiligo and canities represent diminution or absence of normal pigmentation of the skin and hair, respectively. Vitiligo stands in strong contrast to the hyperpigmentation of the skin discussed in this paper. It is beyond the scope of this review to discuss these subjects in detail. Considerable interest now centers in the possibility that the presence of gray hair is in some way related to a deficiency of one or more of the factors

of the vitamin B complex. An appraisal of the therapeutic efficacy of vitamin treatment of gray hair is not warranted at present. The status of this subject is given in two recent reviews.^{377, 378} Undoubtedly there is much to be learned about the systemic causes and associations of gray hair, as witness its occurrence in such widely separated disorders as pernicious anemia, Werner's syndrome²⁰⁸ and the Vogt-Koyanagi syndrome.³⁷⁹

It is of considerable interest that patches of vitiligo not uncommonly coexist in the very skin showing hyperpigmentation. Vitiligo occurs in Addison's disease, hyperthyroidism, scleroderma, arsenic poisoning, pernicious anemia and many of the other diseases with melanin skin pigmentation. These paradoxical combinations at present admit of no clear-cut explanation. Vitiligo may result from a variety of local skin lesions, a subject well

Roumanians, Chinese, Syrians and others. It gives an excellent description of physiologic pigmentation, which is minimal in infancy and complete by the end of the second decade. ³⁸¹ and Greenbaum³⁸¹ discuss in some detail physiologic oral pigmentation. The work of Baker,²⁰ Laidlaw³⁸⁶ and others showed that in the majority of white persons pigment cells (melanoblasts) can be demonstrated microscopically in the mucosa even if pigmentation is not grossly observable. These pigment cells are therefore subject to many of the same factors known to influence similar cells in the skin. It follows that oral pigmentation is of far more clinical significance in a person of light than in one of dark complexion. It is not itself of diagnostic value. Furthermore, many local exogenous pigmentations occur, chiefly from metals, and usually stain the gum and

TABLE 4. Conditions Governing Pigmentation of the Oral Mucous Membranes.*

USUALLY PRESENT	OCCASIONALLY PRESENT	RARELY OR NEVER PRESENT	PIGMENTATION OF MOUTH WITHOUT SKIN PIGMENTATION†‡

†Frequency appears less in the current literature than in the older literature.

‡Bismuth pigmentation of skin (bismuthia) is a great rarity.

§Metals usually present a metallic sulfide line in the gums near the teeth, which is occasionally present more diffusely.

¶For further information on this group see references.³⁸¹⁻³⁸⁴

discussed in the standard textbooks on dermatology. Vitiligo also frequently occurs without any apparent local or systemic cause.

It is, also of interest that Mussio Fournier, Cervino and Conti³⁸⁰ have reported using pituitary melanophore hormone preparation for the treatment of vitiligo, apparently with some success, whether this preparation was given intradermally, locally by electrical transfer or parenterally.

Pigmentation of mucous membranes of mouth. The value and limitations of pigmentation of the mucous membranes of the mouth as a diagnostic sign of systemic disease appear to be poorly understood. Many physicians associate it exclusively with Addison's disease. The literature contains a number of excellent discussions of this subject.³⁸¹⁻³⁸⁵

Oral pigmentation (melanoplakia) is normally a racial peculiarity. Monash³⁸³ demonstrated that only 5 per cent of 200 Negroes showed no pigmented areas in the mouth. During a six-month period he noted oral pigmentation in 30 persons of various racial groups including Italians, Jews, Greeks,

near the teeth and occasionally the tissues elsewhere in the mouth. Not all mouth pigmentation are due to melanin. Furthermore, melanin pigmentation, if deep in the tissues, may look bluish and be confused with cyanosis. Diffuse oral argyria is common. Jaundice is readily detected in the mucous membranes of the mouth, as are all the hemoglobin pigments. Table 4 contains statistics based on the literature that may be of diagnostic value if interpreted in the light of the aforementioned discussion.

External pigmentation of eye. The accompanying presence, and in some cases the persistence, of pigmentation of the various external membranes of the eye—the palpebral and bulbar conjunctivas, sclera and cornea—as related to various skin pigmentations is of considerable general clinical interest and often of diagnostic aid.^{108, 183, 226, 307, 387, 388} At times the nature of the extraocular pigmentary syndrome is pathognomonic. Examination of the eye must be made in a general light, not omitting an oblique view. The use

magnifying lens is helpful. Co-operation with ophthalmologist to secure inspection with a lamp and corneal microscope may enable to detect pigmentary deposits long before they are evident in the skin, for example, in ochronosis and argyria. Observation with fluorescent light enables pigmentation not visible in ordinary light to be seen.³⁰⁷ Table 5 contains information that

Pallor (anemia)		

*Sufficient data to classify every pigmentary disorder are not available, only the combinations found fairly consistently are listed

†See references 327, 328 for further data on these conditions

‡Melanin pigmentations of the skin are only occasionally associated with extraocular melanosis.

§Cyanosis is more difficult to detect in the conjunctiva than in the mucous membranes of the mouth.

may be of some aid in orienting the reader to the diagnostic possibilities of the associations mentioned. The lists are by no means complete, since clear-cut statements concerning extraocular pigmentation in many pigmentary disorders are not given in the available literature. It should not be overlooked that melanoblasts have been demonstrated in the conjunctival mucosa¹⁰⁹ and that in certain diseases they are potentially capable of causing a clinically detectable melanin pigmentation. It is not clear from the literature how frequently extraocular melanosis occurs in the various diseases with skin melanosis. It should not be confused with the pigmentary disturbances of the retina and choroid, for example, retinitis pigmentosa. Rarely a systemic disorder such as Addison's disease causes pigmentation of the retina that can be seen on ophthalmoscopic examination.³⁵⁹

Pigmentation of fingernails. In contrast to the observation of the mouth and eyes, that for changes in the color of the fingernails in systemic disorders with pigmentation is of limited clinical value. That the fingernails may be pigmented was well shown by Monash,³⁹⁰ who found that such pigmentation in Negroes is a normal finding of common occurrence, usually in the form of pigmented longitudinal stripes, and in darker-skinned Negroes in that of a diffuse pigmentation in addition. Pigmentation

of the fingernails may occur in white persons with disorders likely to produce marked melanosis of the skin, such as Addison's disease³⁹¹ (see illustration²⁴⁶). Mees's stripe in arsenic poisoning^{213, 392} may be simulated by other white striae^{393, 394} (see colored plate³⁹⁴). The striped area when shed can be analyzed for arsenic. Argyria causes pigmentation resembling cyanosis, but capillaroscopic examination of the nailbeds reveals a normal capillary blood flow.³⁹⁵ Gold therapy is said to pigment the nails.³⁹¹ Pigmentation of the fingernails during hyperthyroidism has been reported.³⁹⁶ The use of phenolphthalein is listed as rarely causing a bluish discoloration of the fingernails.³⁹⁷

LABORATORY DIAGNOSIS OF THE CAUSES OF SKIN PIGMENTATION

The limitations of the human eye in analyzing the causes of skin color changes should be apparent from what has been written. Spectrophotometric analysis of the skin allows recognition of both the amount and nature of the pigments present, but unfortunately the complicated technic and costly apparatus required limit its use to research studies. Under fluorescent light, some pigmentations not visible to the eye in daylight or artificial light can be readily seen (see illustration³⁰⁷). A routine history and physical examination and the ordinary laboratory work clarify the cause in most cases. The red-cell count and hemoglobin determination reveal an increase or diminution of hemoglobin in the blood. Spectroscopic examination of the blood detects methemoglobinocytopenia, sulfhemoglobinocytopenia, carboxyhemoglobinemia and methemalbuminemia. Cyanosis not due to other hemoglobin derivatives is caused by increased amounts of reduced hemoglobin. Porphyrins can be detected in the urine in porphyria by spectroscopic examination. The quantitative van den Bergh test of serum for jaundice and the Greene-Blackford test for carotenemia are highly specific. Picramic acid and atabrine can be detected chemically in the urine. Rous's test of the urine for hemochromatosis, although not entirely specific, is frequently employed. All these tests are for pigments present in the blood or urine. The Brugsch test⁴³ and the histamine wheal test for jaundice, as well as the Fishback test³⁴⁰ for hemochromatosis, are skin tests occasionally used.

Pigments deposited in the skin tissues may be studied by histologic examination of tissue obtained by biopsy. In a general hospital this method is rarely utilized to its full advantage. Requests are usually made by the physician, who understands but little of dermatology and less of the methods and limitation of histologic study of the skin. Skin biopsy specimens are often taken by a surgeon who not only has a limited knowledge of skin pigmentation but is often further handicapped by being given no specific directions concerning the most desirable

place from which to take the specimen. Unless studies are specifically requested, the pathology department is likely to fix and stain these specimens in the same manner as other types of biopsy material.

It is generally agreed by dermatopathologists that skin biopsy specimens routinely fixed in formaldehyde and stained with hematoxylin and eosin are not adequate for the study of cytology and especially for evaluation of the cause of pigmentation.³⁹⁸ Bloch's Dopa reaction to detect activity of melanoblasts,¹⁶ Masson's trichrome stain for cellular detail,³⁹⁹ silver stains to demonstrate localization and extent of melanin pigmentation, Osborne's method for demonstrating arsenic crystals in the skin,²¹⁷ special fixatives for skin tissue, dark-field examination of sections lightly stained with polychrome methylene blue, which enables one to visualize the various metallic pigment granules, as in argyria and chrysiasis, as refractile granules and excludes the nonrefractile granules of melanin and hemosiderin, spectrographic examination of biopsy tissue for detection of metallic pigments,³⁵⁰ Mallory's potassium ferrocyanide method for staining hemosiderin and Mallory's fuchsin stain for hemofuscin are typical of the many technical approaches available to the skilled dermatopathologist. It is apparent from this review that the cause of many types of melanin pigmentation cannot be determined histologically and that diagnosis depends chiefly on routine clinical and indicated laboratory procedures.

MASSACHUSETTS MEDICAL SOCIETY

PROCEEDINGS OF THE ONE HUNDRED AND SIXTY-THIRD ANNIVERSARY

May 22, 23 and 24, 1944

THE one hundred and sixty-third anniversary of the Massachusetts Medical Society was observed in Boston on Monday, Tuesday and Wednesday, May 22, 23, and 24, 1944, at the Hotel Statler. Fourteen hundred and forty physicians were registered.

MONDAY, MAY 22

The supervising censors met at 5:00 p.m. in Parlor D.

The Cotting Supper was served to 197 councilors in Parlors A and B. The annual meeting of the Council was held in the Georgian Room, at 7:00 p.m. There were 218 councilors in attendance.

TUESDAY, MAY 23

The first general session was presided over by Dr. George L. Schadt and Dr. G. Lynde Gately, acting as chairman and co-chairman, respectively. The attendance was as high as 650.

This session took the form of a symposium on war injuries.

The one hundred and sixty-third annual meeting of the Society was held at 11:00 a.m. in the Georgian Room. Dr. Roger I. Lee presided. The attendance was 450.

Dr. Lee spoke at length on the state of the Society. The annual oration entitled "A Toxic Factor in

Experimental Traumatic Shock," was delivered by Dr. Joseph C. Aub.

During the course of the meeting the President presented Dr. George Mathews, of Providence, delegate from the Rhode Island Medical Society, and Dr. G. Gardiner Russell, of Hartford, delegate from the Connecticut State Medical Society. They responded fittingly.

The annual luncheon was served in Parlors A, B and C to 156 fellows.

A clinical meeting was held in the Georgian Room from 2:00 to 4:00 p.m., under the chairmanship and co-chairmanship of Dr. Dwight O'Hara and Dr. Clifton T. Perkins, respectively. The attendance was 600.

The Shattuck Lecture was delivered at 4:00 p.m. by Dr. Alfred Blalock, of Baltimore, Maryland. Dr. Blalock's subject was "A Consideration of Recent Advances in Surgery." (This lecture will appear in the *New England Journal of Medicine*, issues of August 17 and 24.)

The annual dinner was held in the Georgian Room at 7:00 p.m. with 492 in attendance. This dinner was graced by the presence of the Honorable Leverett Saltonstall, Governor of Massachusetts. William Cunningham, of the *Boston Herald*, was the principal speaker.

WEDNESDAY, MAY 24

There was a general clinical meeting in the Georgian Room from 9:00 a.m. to noon under the chairmanship and co-chairmanship of Dr. Charles F. Wilinsky and Dr. Leroy E. Parkins, respectively. The attendance was 600.

From 12:00 noon until 2:00 p.m. a series of section meetings and luncheons was held.

The Section of Medicine, under the chairmanship of Dr. George D. Henderson, met in Parlor B. Because of the numbers attending, it was adjourned to the Georgian Room. Sixty-two sat down for luncheon, and approximately 300 attended the clinical meeting afterward.

The Section of Surgery, under the chairmanship of Dr. Howard M. Clute, met in Parlor C. The attendance was 65.

The Section of Pediatrics, under the chairmanship of Dr. Leroy T. Stokes, met at The Junior League, Zero Marlboro Street. The attendance was 54.

The Section of Obstetrics and Gynecology met in Parlor A, under the chairmanship of Dr. Christopher J. Duncan. The attendance was 62.

The Section of Radiology met in Room 716 W, under the chairmanship of Dr. Stanley A. Wilson. The attendance was 25.

The Section of Physiotherapy met in Parlor E, under the chairmanship of Dr. Wilmot L. Marden. The attendance was 13.

The Section of Dermatology and Syphilology met in the Hancock Room, under the chairmanship of Dr. John G. Downing. The attendance was 35.

The New England Society of Anesthesiology met in Parlor D. The attendance was 32.

From 2:00 to 5:00 p.m. a general clinical meeting was held in the Georgian Room under the chairmanship and co-chairmanship of Dr. Daniel B. Reardon and Dr. Vlado A. Getting, respectively. The attendance varied from 450 to 600.

There were eighteen scientific and seventy-six technical exhibits.

The motion pictures, as usual, attracted a large number.

The official list of officers, standing and special committees, councilors, censors, admissions, deaths and so forth are appended.

MICHAEL A. TIGHE, *Secretary*

ANNUAL MEETING OF THE SOCIETY

The one hundred and sixty-third annual meeting of the Massachusetts Medical Society was called to order by the president, Dr. Roger I. Lee, in the Georgian Room of the Hotel Statler, Boston, at 11:00 a.m., May 23, 1944. There were approximately 450 fellows present.

The Secretary offered the record of the last annual meeting as published in the *New England*

Journal of Medicine, issue of July 22, 1943. There being no objection, this report was declared accepted by the chair.

Dr. Lee presented Dr. George Mathews, of Providence, representative of the Rhode Island Medical Society. Dr. Mathews brought the greetings of the society.

Dr. G. Gardiner Russell, of Hartford, Connecticut, was introduced and brought the greetings of the Connecticut State Medical Society.

The Secretary announced that the membership of the Massachusetts Medical Society, as of May 23, 1943, was 5753, and as of May 23, 1944, 5778. He said that 104 fellows had died, 11 had resigned and 1 had been deprived of membership during this interval. He added that 129 new fellows had been created and that 12 had been reinstated during this period. The net gain in membership, he said, was 23.

The following amendments to the by-laws were read by Dr. Lee:

Chapter IV, Section 4, of the by-laws of the Massachusetts Medical Society is amended by striking out the word "stated" appearing in the first line and inserting in its place the word "annual," by deleting the words "in October" appearing in the second line, by striking out the word "stated" in next to the last line and inserting in its place the word "annual" and by deleting in the last line the words "in February."

The amended section reads as follows:

Section 4. The Council shall elect at the annual meeting, on nomination by the President or from the floor, the Auditing Committee, composed of two fellows who are not councilors.

This committee following the close of the fiscal year, shall require by a certified public accountant an examination of the assets and securities of the Society in the custody of the Treasurer, and of the Treasurer's books and accounts.

This committee shall verify the accountant's examination and report its findings at the annual meeting of the Council.

Chapter VI, Section 5, of the by-laws of the Massachusetts Medical Society is amended by striking out the word "February," as it appears in the fifth line of page 21, and inserting in its place the word "annual."

This amended paragraph reads as follows:

He [the Treasurer] shall render to the Council at its annual meeting a full written report of the assets and liabilities on December 31 of the previous year, and also of the financial transactions of the Society during that year.

Dr. Lee said that the purpose of these changes was to allow more time for the auditors to do the job assigned them under the by-laws. He added that they had been favorably acted upon by the Council on May 24, 1943.

Dr. Frank R. Ober, Suffolk, moved the adoption of these two amendments. This motion was seconded by Dr. Clarence E. Burt, Bristol South, and it was so ordered by vote of the members.

Dr. Lee called on Dr. William H. Robey, Suffolk. He presented resolutions on the death of Dr. Charles S. Butler, former treasurer of the Massachusetts Medical Society. These resolutions appear on

records of the meeting of the Council held on 22, 1944.

r. Lee made an urgent plea to the district secretaries to send to Dr. Tighe the names of all physicians who had entered the armed services from their respective districts.

r. Lee called on the vice-president, Dr. Daniel Reardon, Norfolk South, to assume the chair. So doing, Dr. Reardon spoke as follows:

As your vice-president, it has been my privilege and pleasure for the past year to work with our president. I have found him an untiring, zealous and hard-working individual. He has not alone confined his time and efforts to the welfare of the Massachusetts Medical Society, but as you well know, is chairman of the Board of Trustees of the American Medical Association. To both these offices he has given time and efforts for the welfare of the medical profession in general.

It is now my distinct honor and pleasure to give you Dr. Er I. Lee, president of the Massachusetts Medical Society, who will report on the state of the Society.

Dr. Lee responded as follows:

It is a happy custom that the president of the Massachusetts Medical Society reports on the affairs of the Society at the annual meeting.

Your present incumbent finds great pleasure in making his report. Any report at this time, however, is made under the shadow of a grim catastrophe that has enveloped the entire world. It has dislocated all our lives. It has dominated all our thoughts. Of necessity, winning the war is the sole objective of all of us. We that are here are under orders if in uniform, under sentence if in civilian clothes. Perhaps a third of the fellows of this society are in uniform, and before long, as the war continues and as recent graduates go into the armed services, approximately half the active physicians of the Commonwealth will be in uniform. It is, I believe, an extraordinary tribute to the unwavering loyalty and the altruistic idealism of the medical profession that no attempt has been made to capitalize on the pressing necessity for doctors in the armed forces or on the resulting shortage of doctors on the home front. There are no doctors' blocs seeking special class legislation. There are no doctors' strikes. There are no doctor profiteers. This is no doctor "black market." And I desire to pay tribute to the wives and families of the doctors in the service. Doctors volunteer. There has been no drafting of doctors, unless one means that a man's conscience drafted him. Doctors volunteered for their soldiers' pay, not for "cost plus" and not for war workers' pay, and their wives make what shift they can. And when these men come back, let these sacrifices be not forgotten.

And in passing may I give a bit of tribute to the wives of the doctors who stayed at home! They have done double duty, quite unheralded and quite unsung. And most of the doctors' patients have, in this trying situation, been understanding and co-operative, and have cheerfully foregone on many occasions the comfort of the doctor's visit, if in his judgment a visit was not absolutely necessary.

The Massachusetts Medical Society operates through committees, which report to the Council. Four of these committees are composed of one man from each district society, elected by the district society. These are the Nominating Committee, although technically not a committee, the Committee on Public Relations, the Executive Committee and the Committee on Legislation. The nominating councilors from each district have the sole function of nominating the officers of the Society. The Committee on Public Relations is perhaps a dozen years old. This committee has been so strikingly useful along the lines of its designation that two quite new committees — the Executive Committee and the Committee on Legislation — have been set up along similar but not identical lines for their particular purposes. The president of the Society, who is an *ex-officio* member of all committees, is

named as the chairman of the Committee on Public Relations and of the Executive Committee. It is not my purpose to repeat the story of the activities of the various committees; it is rather to discuss the functioning of the committee mechanism of the Society, inasmuch as the Society operates through committees reporting to the Council.

The Executive Committee was designed for two purposes: to free the Council from considerable detail and to provide a group, informed before the Council meeting, concerning certain committee reports and other items of a complex nature. Although there has been some confusion about the extent of the authority of the Executive Committee, it is my considered opinion that this committee, which has worked very diligently, has contributed much to the thorough consideration of problems so that the Council might act wisely. It is, I believe, of great benefit to the Society that free preliminary discussion of certain questions can take place in a large representative committee like the Executive Committee, and indeed, certain problems are gone over by the Committee on Public Relations before consideration by the Executive Committee.

These four committees, excluding the *ex-officio* members, are composed of seventy-two men. Naturally some of these are duplicates. On the other hand, there are alternate members of the Executive Committee. And this number refers only to four committees, all elected by the member districts.

Most of the committees of the Society, whether standing or temporary, are small. The ordinary procedure is that the president nominates and the Council elects. The Council may also nominate. Most committees consist of five members. But there are larger committees, notably a committee of seventeen, appointed to consider a loan fund for returning medical officers of the Society. There are around 250 fellows serving on all these committees. The majority of the members of the committees are members of the Council. The chairmen of the standing committees are *ipso facto* members of the Council. The Council numbers at this time 328. The number of fellows in the Society is about 5778.

Your president has always believed that service on the committees of the Society was both an obligation and an opportunity and should be freely shared by the fellows and that committee membership should be frequently changed. He also has strongly believed in the liberal mixture of young and old in committees. Alas for his theories. The war took off the younger men. Older men, familiar with certain committee duties, could carry on effectively with a minimum of effort. So, very regretfully, committees were frozen. But when the war is over and the fellows come back, I want this to be a public record of what one president feels regarding committee changes. I should like also to suggest a slower pace of change in some of the committees, such as the Committee on Ethics and Discipline and the Committee on Finance. I believe, too, that this should also apply to the delegates to the House of Delegates of the American Medical Association. I do not believe, however, that any committee should be regarded or regard itself as fixed.

Each of the Society's committees has made a report to the Council. These reports will be printed in the *Journal* in the near future and therefore will not be considered here.

Reports may not be very revealing. The Committee on Ethics and Discipline has a talent that approaches genius in laconic statement. Its activities are mostly confidential. The time spent by this committee is enormous. The good to the Society is incalculable.

A recent committee that has labored quietly but effectively is the Medical Advisory Committee to the Regional OPA. No fire alarms, no sirens, but some hefty spade work and a lot of sweat, and a good crop at the end. Washington says it is the best advisory committee in the country.

During this session, we have had frequent cause to be grateful to the Committee on Arrangements. Dr. Gordon Morrison reluctantly consented to remain on the job again this year. He and his hard-working committee have done a grand job. What does not appear on the surface is the liaison that Dr. Morrison has maintained between his

committee and the committees of other organizations on war meetings.

I saw Dr. Walter P. Bowers the other evening in Worcester. He said to me, "Now, don't you ever forget that I picked out Nye as editor of the *Journal*." I had thought that the Committee on Publications had picked Nye. Bill Breed claims that he discovered Nye. Under the ownership of the Massachusetts Medical Society, the *Journal* (by which I mean, of course, the *New England Journal of Medicine*) has had but two editors — Dr. Bowers and Dr. Nye. The Committee on Publications selects the Shattuck Lecturer and gives some heed to the publication of the *Directory*, and ostensibly to the *Journal*. I have been a member of that committee with Dr. Bowers as editor and with Dr. Nye as editor. I seem to recall that I announced to the Council the appointment of Dr. Nye. But, in any event, the *Journal* has prospered wonderfully in these war times. As you know, fellows in the armed forces are excused from dues, including subscription to the *Journal*. Some of us thought that, with diminished subscriptions, paper shortage and inability to take advertising, the Society might be in for a considerable loss in the *Journal* account. But, at the moment, the circulation is increasing. As a humble contributor, I can testify that requests for reprints come from nearly every state in the Union. You have every reason to be proud of the *Journal*, the editor, the editor emeritus and the Committee on Publications.

The financial status of the Society seems excellent. The new treasurer, Dr. Hubbard, has given generously of his time and energy. There is now set up a system of expert advice on securities and of modern accounting.

The additional space for the officers of the Society has permitted a considerably increased volume of work of the Society to be carried on smoothly. For example, there are sometimes as many as four committees of the Society meeting at once. Wednesday seems to be the day that the doctor takes a busman's holiday and goes to 8 Fenway, Boston, for a committee meeting of the Massachusetts Medical Society.

As you may know, plans are already under active discussion to establish an information bureau at the Society's headquarters.

As a part of his duties, the president has the privilege of visiting the district societies. This was indeed a pleasure, and it is a matter of deep regret that it was not possible to visit all the district societies. Despite the handicaps and obstacles of wartime conditions, the district societies have been able to continue to hold interesting meetings with good attendance.

Under the authority of the Executive Committee, which was subsequently approved by the Council, a committee from the Society met several times with representatives of the other New England State medical societies for discussion of legislative matters. This idea did not originate in this state. It seems to be generally true, if the New England states are a criterion, that doctors are largely uninformed concerning possible legislation involving the practice of medicine. Being uninformed the profession is often unable to bring to any discussion the benefits of its experience. Then, too, the uninformed are frequently led into unwise, irrelevant and perhaps inaccurate remarks, which are not helpful to orderly discussion. It would seem the plain duty of every member of the profession to acquaint himself fully with the various and sundry legislative proposals; he should study these proposals in the light of his own knowledge of the facts. Some of these problems are today as unanswerable as the cure of cancer or the prevention of the common cold.

Doctors are citizens and as such are entitled to political beliefs and political affiliations. But in the discussion of medical service to the people, political beliefs and political affiliation have no place. So long as the Massachusetts Medical Society is recognized as unselfish and altruistic, just so long can it expect to have its voice listened to with respect.

It is pleasant to record improvement in the relations between the Society and the regularly instituted legislative, executive and health authorities on Beacon Hill. The medical profession has no selfish interest of its own

to further. It does have a wealth of experience and knowledge that should be made available for the better of the public. The past year promises to be epochal in the standards of medical practice in Massachusetts, and if nothing unforeseen happens, the year 1944 will define the Commonwealth of Massachusetts from its unenviable position of being the dumping ground of gradedly actual, nominal or what you will, of unapproved medical schools. There is now an excellent Board of Registration in Medicine. All this comes as the result of years of effort to secure a good medical-practice Act, which is now law in Massachusetts. In this state, medical standards have suffered grievously because of excessive lay domination over the medical profession. In a recent address at the one hundred and fiftieth anniversary of the Worcester District Medical Society, I took occasion to point out that lay thought and lay influence had controlled the medical profession from the days of the medicine man to the present day. The best medical school in the country, the best hospital in the country or the best and most progressive medical society in the country does not set medical standards; but legislatures do. I am far from advocating unrestricted medical control. I admit that penicillin is a product of war conditions and that it is doubtful how penicillin would have been developed without the war. One seemingly cannot have penicillin without the war. But my sole point is that doctors do not have sufficient voice in the determination of many medical problems, particularly that concerning the standards of medical practice.

There are many fellows of the Society who have made the past year a pleasant one for the outgoing president. There is one person, not a fellow, to whom I have been indebted on many occasions for never-failing courteous co-operation, our executive secretary, Bob Boyd. And there is one fellow, who is in one person a seeing eye, a watchdog, a life-saving St. Bernard, and man's and president's best friend — the secretary of the Society, Mike Tighe.

(Dr. Lee's address, which showed not only intimate knowledge of the Society in all its affairs but likewise a very human understanding of its problems with which the war has confronted its members, was greeted with loud applause.)

Dr. Lee resumed the chair and introduced the new officers:

President: Elmer S. Bagnall, Essex North
Vice-president: Sumner H. Remick, Middlesex South
President-elect: Reginald Fitz, Suffolk
Secretary: Michael A. Tighe, Middlesex North
Treasurer: Eliot Hubbard, Jr., Middlesex South
Assistant treasurer: Norman A. Welch, Norfolk
Orator: Frank H. Lahey, Suffolk

All responded fittingly.

The President expressed his pleasure in presenting the distinguished orator, Dr. Joseph C. Aub, Boston, whose subject was "A Toxic Factor Experimental Traumatic Shock." (At the close of his oration Dr. Aub was loudly applauded. His oration will appear in the *New England Journal of Medicine*, issue of July 20, 1944.)

Dr. Reardon moved that the meeting adjourn. This motion was seconded by a member, and it was so voted.

Dr. Lee declared the one hundred and sixty-third annual meeting of the Massachusetts Medical Society adjourned at 12:20 p.m.

MICHAEL A. TIGHE, Secretary

APPENDIX

ADMISSIONS RECORDED FROM MAY 25, 1943, TO MAY 23, 1944

YEAR OF ADMISSION	NAME AND RESIDENCE	MEDICAL SCHOOL
1944	Alba, Anthony, Dorchester	Tufts
1943	Alpert, David Robert, Allston	Tufts
1943	*Alifano, John James, Springfield	Middlesex
1943	Anderson, Donald Grigg, Boston	Columbia University
1943	Anderson, Dorothy Sperling, Newton Lower Falls	Boston University
1944	Anderson, Erna Goettsch, Boston	Columbia University
1943	*Annis, Israel Alan, Auburndale	Middlesex
1943	Armstrong, Sinclair Howard, Jr., Boston	Harvard
1944	*Avallone, Louis John, Somerville	Middlesex
1943	Baker, Joseph Michael, Springfield	University of Vermont
1944	Bandeian, John Jacob, Bridgewater	Tufts
1943	Barry, Herbert, Jr., Cambridge	Tufts
1944	Beals, Lester H., Mount Hermon	University of Michigan
1944	Belin, Harry, Middleton	Tufts
1943	*Berman, Leo, Brookline	Basel University
1944	Blackmer, Lewis Dwight, Quincy	Tufts
1944	Blodgett, James Bishop, Brookline	Harvard
1943	Boone, Edward William, Boston	Harvard
1943	Booth, Marion Frances, Northampton	University of Nebraska
1943	Boynton, Willard Harold, East Boston	Tufts
1944	Bruno, Francis Ernest, Quincy	Tufts
1943	Bryan, Charles Silas, Jr., Cambridge	Harvard
1943	*Butts, Vincent, East Boston	College of Physicians and Surgeons, Boston
1944	Cahill, George Byron, Boston	University of Minnesota
1944	Carroll, Robert Ernst, Boston	Yale
1944	Chapman, William Phalen, Boston	McGill
1943	*Chase, Frank Hills, Stoneham	Bellevue Hospital Medical College
1944	*Chesnow, Albert, Great Barrington	Middlesex
1944	*Ciampa, Frank, Somerville	University of Naples
1943	*Civen, Eva, Dorchester	Middlesex
1944	Congdon, Frederick Richard, Pittsfield	Tufts
1943	Davidson, George Davis, Quincy	Boston University
1944	*Davis, Robert Armstrong, Wareham	Mid-West Medical College
1943	Dopkeen, Saul Kahn	Boston University
1944	*Drury, George Eliot, Malden	College of Physicians and Surgeons, Boston
1944	*Ehrentheil, Otto Felix, Brighton	University of Vienna
1943	*Ehrlich, Robert, Newton Centre	Middlesex
1943	Engleman, Clarence Clarke, Brookline	Western Reserve
1943	Ewing, Edward Hiltz, Stoughton	College of Physicians and Surgeons, Baltimore
1943	Fell, James Edward, Fall River	Tufts
1944	Finch, Clement Alfred, Boston	University of Rochester
1943	Floyd, Louis Carl, Brookline	University of Texas
1943	Flynn, James Lawrence, Boston	Georgetown
1943	Flynn, John F., Pittsfield	Washington University
1943	*Friedman, Sidney, Brookline	Middlesex
1943	Garrett, John William Douglas, Boston	University of Toronto
1943	Goeringer, Claire Ferdinand, Fort Devens	Johns Hopkins
1943	Hall, Albert Eden, Worcester	Long Island
1944	Halter, Paul Edmund, Boston	Western Reserve
1944	Heerdegen, Dorothy Kathryn, Jamaica Plain	Ohio State University
1944	Heimlich, Fred, Brookline	Tufts
1943	Hemenway, Ruth Victoria, Williamsburg	Tufts
1943	*Hite, Jacob William, Boston	Middlesex
1943	*Hochman, George Victor, Sharon	Middlesex
1944	Holt, William Leland, Amherst	Harvard
1943	Howard, Rutledge William, Boston	Harvard
1944	Howe, Chester W., Brighton	Tufts
1943	Hudson, Henry Alfred, Marblehead	Tufts
1943	*Johnson, Daniel Philip, Melrose	University of Lausanne
1943	Kasdon, Solomon Charles, Boston	Yale
1944	Katz, Harvey Warren, Everett	Tufts
1943	*Kay, Stephen Benjamin, Fitchburg	Middlesex
1944	Kenney, Francis R., West Newton	Boston University
1944	Landis, Eugene Markley, Chestnut Hill	University of Pennsylvania
1943	Leighton, Herbert Towle, Brookline	Harvard
1944	Le Vine, Bernard Elliot, Roxbury	Tufts
1944	Levine, Irving Maxwell, Dorchester	Tufts
1943	*Levy, David Abraham, Mattapan	Middlesex
1944	Lincoln, James Rufus, Wareham	Harvard
1944	Lockhart, Arthur John, Chestnut Hill	Columbia University
1943	Lodge, Edmund Anderson, Gloucester	University of Kansas
1943	Lynam, Patrick Joseph, Malden	Tufts
1943	*Magendantz, Heinz Herbert, Newton Highlands	University of Cologne
1944	*Makofski, Anthony B., Northampton	Kansas City University of Physicians and Surgeons
1944	*Marks, Abraham S., Malden	Middlesex

1943	McCarty, William Charles, Cambridge	Harvard
1943	McGillicuddy, John Joseph, Brighton	Yale
1944	McLaughlin, James Alphonsus, Ocean Bluff	Tufts
1943	McNulty, John Joseph, Roslindale	Tufts

1943	Varnerin, Emma Mary, Roxbury	Boston University
1943	*Vilker, Arthur Hyman, Revere	Middlesex
1944	Votta, Ipolidi John, Boston	Boston University
1943	Waldman, J. Edward, Malden	Tufts
1943	*Werby, Isidore, Brighton	Middlesex
1944	Zonderman, Bernard, Revere	Boston University

Total 129

*The candidate after a personal interview, was approved by the Committee on Membership and permitted to take an examination before a board of censors.

DEATHS REPORTED FROM MAY 23, 1943, TO MAY 23, 1944

ADMITTED	NAME	PLACE OF DEATH	DATE OF DEATH	AGE
1910	†Abbe, Elizabeth Morrison	Roxbury	January 18, 1943	65
1900	†Alfred, James	Brockton	June 12, 1943	69
1883	†Atwood, Charles Augustus	Taunton	October 10, 1943	81
1939	Barrett, James Aloysius	New Bedford	April 28, 1944	55
1941	Barry, Thomas A.	"In the service of his country"	August 4, 1943	34
1914	Bell, Clarence John	Wellesley	June 6, 1943	67
1890	†Blake, John Bapst	Brattleboro, Vermont	August 17, 1943	77
1912	Brady, William Francis	St. Petersburg, Florida	February 28, 1944	53
1887	†Brennan, John Joseph	Worcester	August 26, 1943	79
1908	Broderick, Francis Patrick	Jamaica Plain	February 26, 1943	67
1899	Buehler, George Van Buskirk	Bedford	November 19, 1943	66
1921	Campbell, Charles Macfie	Cambridge	August 7, 1943	70
1898	Carden, Charles James	Tewksbury	July 4, 1943	60
1934	Chase, Lawrence Milton	Carver	February 8, 1944	70
1915	Clarke, Willis Earl	West Somerville	February 23, 1944	55

5	Cochran, John Joseph	Natick	May 1, 1944	47
11	†Colburn, Frederick Wilkinson	Boston	April 9, 1944	73
25	Connor, Thomas John	Arlington	July 16, 1943	51
37	Coriat, Isador Henry	Boston	May 26, 1943	67
95	Coues, William Pearce	Brookline	January 13, 1944	71
27	Cronin, Edward Joseph	Brighton	February 11, 1944	46
19	Curran, Louis Frederic	Dorchester	July 22, 1943	57
11	Cushman, Howard Lewis	Methuen	November 3, 1943	57

CASE 30311

PRESENTATION OF CASE

A thirty-nine-year-old housewife was admitted to the hospital for study.

The patient had been in apparent good health until two years before entry when she experienced intermittent attacks of epigastric pain, following one year of "beer drinking and smoking almost incessantly." The pain was centered in the pit of the stomach and radiated to the right scapula. During the attacks she was unable "to sit or lie still or get her breath." Leaning forward and pressing against the stomach with a pillow brought relief. She was seen by her physician, who attributed her condition to drinking and prescribed some pills and a liquid, which gave some relief. The attacks recurred on an average of once a month and lasted for a few days. About nine months before entry the attacks became more frequent and more severe. At that time she had an episode of jaundice with chills, fever and pain that subsided spontaneously. Following this she had a severe attack of epigastric pain that radiated to the back and along both costal margins. The pain occurred after eating and was accompanied by copious vomiting. This episode lasted for a week, although she was temporarily relieved by medication. Eight months before entry she was admitted to a hospital in another city, where a history of intolerance for fatty and fried foods and a story of constipation for a year were elicited.

Physical examination at that time showed tenderness without spasm in the epigastrium, and tenderness in the left upper quadrant. The blood was normal. A Graham test was positive, although no stones were visualized. A cholecystectomy was performed, and palpation of the common duct revealed no stones. The gastric area was firm and adherent. The pathological diagnosis was chronic cholecystitis. Postoperatively she continued to have abdominal pain. A fluoroscopic examination of the stomach three weeks postoperatively showed a 2-cm. projection on the anterior wall near the lesser curvature and 5 cm. posterior to the pylorus, over which no

peristaltic wave seemed to pass. The films made at the time did not show this finding. Re-examination three weeks later was also inconclusive. In some positions there appeared to be a large ulcer on the posterior wall at about the junction of the middle and lower thirds. The rugae of the entire stomach were coarse and irregular.

A second exploratory laparotomy was performed seven weeks after the first operation. The viscera above the omentum appeared to be densely plastered together, and a preliminary Witzel jejunostomy was performed. The patient was placed on a Sippy diet for five weeks, without improvement. She was finally discharged after six months of hospitalization but readmitted three days later because of recurrence of pain. The gastric contents two weeks after readmission consisted mostly of bile, with no free acid and 20 units of combined acid.

The patient remained in the hospital until two weeks before transfer to this hospital. During that period of hospitalization she had lost 65 pounds. She claimed that she had as much epigastric pain as before operation, but its character was different. It appeared primarily on deep inspiration and radiated bilaterally along both costal borders to the shoulder and arm on the left side. The pain apparently had no relation to meals or to bowel movements. The latter were scanty, light colored and never bloody or tarry. She vomited only rarely. For three days before entry she had been free of pain.

Physical examination showed a well-developed woman in no distress. The heart and lungs were normal. There were an old appendectomy scar in the right lower quadrant, a left rectus scar, and a small cruciate scar in the left flank, all of which were well healed. There was tenderness in the upper abdomen, most marked in the epigastrium, which felt diffusely more tense and resistant than the rest of the abdomen; no definite masses were palpable. Pelvic examination was essentially negative.

The blood pressure was 140 systolic, 95 diastolic. The temperature was 98° F., the pulse 80, and the respirations 20.

The white-cell count was 7300, with 75 per cent neutrophils. The red-cell count was 2,120,000, with 7 gm. of hemoglobin. The urine was negative except for the sediment, which contained innumerable red cells and 6 to 8 white cells per high-power field. A blood Hinton test was negative. The blood non-protein nitrogen was 22.5 mg. per 100 cc., and the protein 7.7 gm.; the chloride was 97 milliequiv. per liter. Gastric analysis revealed no free acid in the fasting sample and 39 units after histamine. A gastrointestinal series showed a normal esophagus. Along the lesser curvature and posterior wall of the body of the stomach and extending down nearly to the angulus was a 7-cm. area of rigidity, which produced a filling defect (Fig. 1). The edges of the latter were smooth. There was no definite shelf, and the mucosal pattern, although slightly irregular,

*On leave of absence.

appeared preserved over the greater portion of this area. No crater could be demonstrated, although one small irregularity was noted that could have been the edge of a fold or a small crater. The remainder of the stomach and the duodenum were not remark-

veloped severe anorexia and was unable to take food by mouth. She was given intravenous fluids. The following day the pain became severer, radiating to both shoulders, the precordial region and the neck. A Levine tube alleviated the vomiting, and the pain

FIGURE 1. *Roentgenogram of the Stomach following a Barium Meal.*

able. Gastrosocopy on the second day revealed a normal antrum that appeared to be directed somewhat anteriorly. The body and lower portions of the fundus were well visualized, and the mucosa was everywhere intact. There were some adherent secretions on the posterior wall high in the body, and the mucosa in this region appeared fixed. There was no inflammation of the gastric mucosa.

The patient was placed on a six-meal bland diet and was given morphine for pain. For the first two days she did well. On the third day she had considerable retching and vomiting and abdominal pain. She de-

veloped severe anorexia and was unable to take food by mouth. She was then given daily intravenous fluids and several transfusions.

On the tenth hospital day an exploratory laparotomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. ROBERT R. LINTON: This thirty-nine-year-old patient was undoubtedly suffering from some form of gastric tumor. The original history quite obviously suggests gallstones, because she had pain in the epigastrium that radiated to the right scapula, and also associated with it she had one attack of jaundice.

the surgeon who saw her originally had a right suspect gall-bladder disease and cholelithiasis. She gave a story of having had copious vomiting. Copious vomiting in the presence of cholelithiasis is rather unusual and would have made me suspect that perhaps there was something in addition. I should also like to point out the fact that the Gram test was reported as positive, although no stones were visualized. It is our belief here — Dr. Robbins correct me if I am wrong — that just because the gall bladder does not show by cholecystogram does not mean disease of the gall bladder. It just means that the dye has not been absorbed in the biliary tract. I am never satisfied with the diagnosis of cholecystitis merely because of the absence of a gall-bladder shadow.

The operation bears out the fact that the gall bladder was not particularly abnormal. It was noted that that operation that she had some lesion in the region of the stomach, which apparently was not investigated too thoroughly. As a result of re-examination by x-ray she had a second exploratory laparotomy, and again the surgeon was unable to make up his mind what the trouble was in the stomach. They did a preliminary Witzel jejunostomy. I do not know why. We do a jejunostomy essentially for feeding purposes if we anticipate a major abdominal operation involving the stomach, so that we can get the patient into better condition. Possibly that is what was planned, but the patient was never in good condition for an operation.

DR. BENJAMIN CASTLEMAN: A portion of the operative note from the other hospital is as follows:

Under spinal anesthesia a left upper rectus incision was made and carried up to the sternum. The peritoneum, stomach, omentum and lesser curvature were all plastered down with edematous adhesive peritonitis. Below the omentum, however, there was no evidence of generalized peritonitis. The lesser peritoneum was opened by going through the gastrocolic ligament; this was found to be adhesive. There was no question of being able to do a gastrectomy. It was therefore decided that the best thing that could be done for the patient was to perform a Witzel jejunostomy for feeding purposes, thus by-passing the stomach.

DR. LINTON: When the patient was finally admitted here, the salient points about the laboratory examinations are that she had marked anemia and a hemoglobin of 7 gm. The urine contained many red cells, which we shall have to discount because we have no proof that it was a catheter specimen.

I should like to see the films of the gastrointestinal series that was done here.

DR. LAURENCE L. ROBBINS: This is the area along the lesser curvature in which the defect was found. It is best seen on the spot films. You will notice that the mucosa appears to be intact on all the spot films. There is only one thing that suggests the possibility of a minute ulceration, but it has more the appearance of a fold of the mucosa on end rather than a crater. I do not see anything that suggests the

shelflike margin of a carcinoma and certainly nothing that looks like a definite crater.

DR. LINTON: Examination of the stools bears that out, since they were negative for blood. Presumably there was no ulcer of the mucosa.

I am a little disturbed in making a diagnosis of tumor of the stomach in a patient who had had so much pain. I am unable to figure out why she had so much pain.

The first possibility is a gastric ulcer. That would explain the pain; but I do not see any evidence of it, and we have no other lead for that diagnosis. Apparently the pain was not affected by food, so I think that we can rule out ulcer on the history and also on the x-ray findings.

That leaves us with some kind of tumor of the stomach. The two that I am thinking of are a scirrhus type of carcinoma that had not ulcerated the gastric mucosa but was traveling in the submucosa and a leiomyoma or leiomyosarcoma. I believe that most leiomyosarcomas give a history of gastric hemorrhage, and this patient had no such history. The fact that she had lost a lot of weight and the fact that she had a marked secondary anemia make me think that she had a malignant lesion rather than a leiomyoma. For that reason I have to make the diagnosis of a scirrhus type of carcinoma of the stomach.

DR. FRANCIS D. MOORE: Were films of the chest taken? The patient had so much pleural pain on both sides around the costal margins that it would be interesting to see what the chest showed.

DR. ROBBINS: None were taken here. The chest was fluoroscoped during the gastrointestinal examination, and apparently nothing suspicious was observed.

DR. CASTLEMAN: None were taken at the other hospital.

CLINICAL DIAGNOSIS

Carcinoma of stomach.

DR. LINTON'S DIAGNOSIS

Carcinoma of stomach, scirrhus.

ANATOMICAL DIAGNOSES

Subdiaphragmatic and peritoneal abscess, left, old. Chronic adhesive peritonitis of upper abdomen, marked.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The operative note reads as follows:

The scar of the paramedian incision was excised. There were several areas of fat necrosis in the wound. A hard fixed mass involved the stomach and pancreas. This was adherent to the liver as well as to the retroperitoneal structures. The whole process felt like extensive malignant disease. There was no apparent fat necrosis inside the abdomen itself. The origin of the tumor could not be determined.

The patient died six days following operation. At autopsy, on opening the abdominal cavity, we found, especially on the left side, large numbers of dense, tough, fibrous adhesions. They involved the whole upper abdominal cavity, particularly the left subdiaphragmatic region. When the adhesions on the left side between the inferior surface of the stomach and the abdominal wall were separated, a large abscess was broken into; this measured about 10 by 4 by 3 cm. and apparently was the mass that was felt at the previous operation. A few small abscesses were also found. Further dissection showed only extensive adhesions. The mucosa and wall of the stomach were perfectly normal.

What the fundamental disease was at the onset of symptoms, I do not know; but I should guess that most of the pain that followed the first operation was due to the abscess and the extensive adhesions that were being formed.

DR. MOORE: Was this a colon-bacillus abscess?

DR. CASTLEMAN: The abscess was not cultured. The wall was thick and made up of granulation tissue. It must have been there for a long time.

DR. LINTON: The abstract gives only one temperature reading, which was 98°F. Did she have fever at any time?

DR. CASTLEMAN: The chart was normal except for one rise to 101°F.

DR. LINTON: Do you think that this was a pancreatitis with abscess formation?

DR. CASTLEMAN: We sectioned the pancreas and could not find any evidence of disease. We considered that diagnosis at the time of autopsy but found no evidence of fat necrosis except in the abdominal incision, which one finds without pancreatitis.

DR. LINTON: She still might have had a perforated ulcer.

DR. CASTLEMAN: We looked carefully for evidence of an old ulcer but could not find even a suspicious area.

It might be interesting to read the interpretation of the radiologist, which is as follows:

The findings are those of an area of rigidity along the lesser curvature of the body. It is possible that this represents intramural extramucosal involvement due to an inflammatory process as a result of a previously perforated ulcer. If one is to consider tumor, it would probably be one of the spindle-cell group. Suggest gastroscopy.

DR. ROBBINS: That was only because it had been reported to me that there had been an ulcer and I could not find it.

CASE 30312

PRESENTATION OF CASE

A forty-one-year-old Irish housewife was admitted to the hospital because of nausea and abdominal pain.

The patient had been in good health until about one year prior to admission, at which time she began

to experience nausea in the morning unassociated with meals and wearing off by noon. There was vomiting. She also noticed a tearing pain in the left upper quadrant of the abdomen on bending over. Eight months prior to entry she developed severe back pain, apparently in the region of the kidney coming on at night or during damp cold weather. She had had no hematuria or other urinary complaints. These attacks diminished as the weather became warmer. For about the same length of time she had noted a burning sensation over the left side of the face and extending downward to the breast and flank. During this period she had increasing fatigue. The nausea became progressively worse and was aggravated by food and exertion. During the three months prior to admission she developed a burning sensation in the hypogastrium associated with diminution in the burning over the face and chest, and a bearing-down sensation in the pelvis. On examination at another hospital she was told that her spleen was enlarged. She was referred to this hospital for study.

The family history except for renal disease in her mother, maternal aunt and maternal grandfather was noncontributory. The patient had worked in a rubber factory some years previously and had been exposed daily to benzol fumes over a period of eight years. For the three years prior to admission her menstrual periods had become irregular and scanty and she had been experiencing hot flashes, chill feelings and bouts of sweating, all of which had diminished in intensity.

Physical examination on admission revealed a well-developed and well-nourished woman in no discomfort. A few prominent veins were present on the chest. Several fixed nodes were felt in the right axilla. The heart and lungs were normal. The spleen was palpable five fingerbreadths below the costal margin, and was firm and nontender. The liver was not felt.

The blood pressure was 120 systolic, 80 diastolic. The temperature was 99°F., the pulse 92, and the respirations 20.

Examination of the blood revealed a white-cell count of 3100, with 71 per cent neutrophils, 23 per cent lymphocytes, 5 per cent monocytes and 1 per cent eosinophils; there was some decrease in the platelets, and a definite shift of the neutrophils to the left, with numerous band forms. The red-cell count was 3,900,000, with 9 gm. of hemoglobin. The mean corpuscular volume was 97 millimicrons and the mean corpuscular hemoglobin 22 millimicrograms. The urine was repeatedly negative. The sedimentation rate was 42 mm. per hour, and 0.65 mm. per minute (corrected). The serum protein was 6.2 gm. per 100 cc., with an albumin-globulin ratio of 1.2. The blood cholesterol was 128 mg., the calcium 12.4 mg., and the phosphorus 3.9 mg. per 100 cc. The prothrombin time was normal. A bromsulfalein test revealed only 10 per cent re-

tion of the dye. A van den Bergh test and the urobilinogen were normal. A red-cell fragility test was normal. An agglutination test for brucella was negative. Tuberculin tests in dilutions up to 1:100 were negative. A blood Hinton reaction was negative. A gastric analysis revealed 47 units free acid thirty minutes after histamine.

An x-ray examination of the chest showed the right middle lobe to be slightly decreased in size, with areas of scarring and fibrosis; the remainder of the lung fields was clear. A plate of the abdomen revealed a markedly enlarged spleen, but the liver shadow was within normal limits. Roentgenographic examination revealed a normal esophagus. Examination of the femurs showed that the cortices of the lower portions of both bones were slightly thinner than normal, with a slight bulge about 10 cm. above their lower ends. The tibias, fibulas and humeruses were negative. A sternal bone-marrow biopsy revealed normal marrow.

On the twenty-sixth hospital day a splenectomy was performed.

DIFFERENTIAL DIAGNOSIS

DR. WYMAN RICHARDSON: I am going to tackle this problem by asking the question, Why was splenectomy performed?

The reasons for doing splenectomy, aside from a surgical condition such as splenic abscess or ruptured spleen, are hemolytic anemia, especially the familial hemolytic anemia, in which it is very successful, thrombopenic purpura, in which it is successful in 85 per cent of the cases, and perhaps thrombosis of the splenic vein, in which, in my experience, recurrence of hemorrhage, the reason for doing the splenectomy, is frequent. What else might one do it for? One may also take out a big spleen, such as the spleen found in Gaucher's disease, or occasionally in malaria, simply because it is so big. Of these possibilities everything has been ruled out except thrombosis of the splenic vein, and we have no evidence that such a condition was present. I shall come back to that in a moment.

I shall now take up the case from the clinical side. At the risk of being repetitious, I shall say in the first place that I think a blood smear in this case would be a fundamental thing to have seen, because the blood picture was peculiar and there is no mention here regarding the red cells—whether there was evidence of regeneration and polychromatophilia. In reading the history one gets the impression that something quite generalized was going on that had little to do with the weight of a large spleen. There were nausea and difficulty with food, neither of which has been explained. There was a tearing pain on bending over. Was that the pain of a large spleen, or pain from a lesion in the back? It seems to me that this was the pain of a lesion of the spine, with involvement of nerve roots. There was a burning sensation over the left side of the face, which also

involved the left side of the chest and flank—just where “the flank” is, I am never sure. How can one explain that? Was it on the basis of diffuse bone involvement, or was it a peripheral neuritis, or was it some sort of functional or emotional type of reaction? In addition, she had a bearing-down pain in the pelvis, which is hard to explain but may have been on the basis of some involvement of the nerve roots. The nausea is still unexplained.

Then we come to the question of exposure to benzol. I agree with Dr. Hunter that the safe amount of benzol to have in the air is zero. It is becoming more and more apparent that exposure to benzol can do anything to the blood picture. If there is exposure to large amounts of benzol, rather acute exposure, for weeks or months one finds the picture that we used to think was characteristic; that is, the process starts with granulocytopenia, goes on to thrombopenia and anemia and ends up with aplastic anemia or pancytopenia, an extremely serious clinical picture, which is sometimes relieved by transfusion. If there is exposure to minimal amounts of benzol over a long period of time one finds an entirely different picture: polycythemia, which is indistinguishable from true polycythemia, leukemia, which is indistinguishable from true leukemia, or finally a picture that has been referred to as “myeloid metaplasia” or extramedullary blood formation occurring in the spleen.

What about the picture we are presented with here? There was no granulocytopenia. In fact, the striking thing is that the leukopenia was a total leukopenia. This is not the picture that one sees with simply a congested spleen due to splenic-vein thrombosis or to portal cirrhosis, because when leukopenia results from a congested spleen it is almost always due to a reduction in the granulocytes. It is certainly not the picture that one sees with acute benzol poisoning. Furthermore, a bone-marrow biopsy was reported as negative. So, somewhat reluctantly, I am going to give up the idea that these findings were due to benzol poisoning.

Physical examination does not help us except for the fact that fixed nodes were felt in the right axilla. Apparently they did not make a great impression on the people taking care of this patient because nothing more is said about them.

DR. BENJAMIN CASTLEMAN: I might read what one observer said: “In the axilla there appear to be enlarged lymph nodes. If they are nodes, they are fixed.”

DR. RICHARDSON: That makes it a little different. I shall come back to the nodes in a minute.

Let me point out that the blood showed a macrocytic hypochromic anemia, which is striking and rather rare. When seen, it is usually in adults who have experienced blood loss for an unusually long period. There is no such story here, so that either the mean corpuscular volume was wrong or there were present in the blood smear large cells, probably

The patient died six days following operation. At autopsy, on opening the abdominal cavity, we found, especially on the left side, large numbers of dense, tough, fibrous adhesions. They involved the whole upper abdominal cavity, particularly the left subdiaphragmatic region. When the adhesions on the left side between the inferior surface of the stomach and the abdominal wall were separated, a large abscess was broken into; this measured about 10 by 4 by 3 cm. and apparently was the mass that was felt at the previous operation. A few small abscesses were also found. Further dissection showed only extensive adhesions. The mucosa and wall of the stomach were perfectly normal.

What the fundamental disease was at the onset of symptoms, I do not know; but I should guess that most of the pain that followed the first operation was due to the abscess and the extensive adhesions that were being formed.

DR. MOORE: Was this a colon-bacillus abscess?

DR. CASTLEMAN: The abscess was not cultured. The wall was thick and made up of granulation tissue. It must have been there for a long time.

DR. LINTON: The abstract gives only one temperature reading, which was 98°F. Did she have fever at any time?

DR. CASTLEMAN: The chart was normal except for one rise to 101°F.

DR. LINTON: Do you think that this was a pancreatitis with abscess formation?

DR. CASTLEMAN: We sectioned the pancreas and could not find any evidence of disease. We considered that diagnosis at the time of autopsy but found no evidence of fat necrosis except in the abdominal incision, which one finds without pancreatitis.

DR. LINTON: She still might have had a perforated ulcer.

DR. CASTLEMAN: We looked carefully for evidence of an old ulcer but could not find even a suspicious area.

It might be interesting to read the interpretation of the radiologist, which is as follows:

The findings are those of an area of rigidity along the lesser curvature of the body. It is possible that this represents intramural extramucosal involvement due to an inflammatory process as a result of a previously perforated ulcer. If one is to consider tumor, it would probably be one of the spindle-cell group. Suggest gastroscopy.

DR. ROBBINS: That was only because it had been reported to me that there had been an ulcer and I could not find it.

CASE 30312

PRESENTATION OF CASE

A forty-one-year-old Irish housewife was admitted to the hospital because of nausea and abdominal pain.

The patient had been in good health until about one year prior to admission, at which time she began

to experience nausea in the morning unassociated with meals and wearing off by noon. There was no vomiting. She also noticed a tearing pain in the left upper quadrant of the abdomen on bending over. The sedimentation rate was 42 mm. per hour, and 0.65 mm. per minute (corrected). The serum protein was 6.2 gm. per 100 cc., with an albumin-globulin ratio of 1.2. The blood cholesterol was 128 mg., the calcium 12.4 mg., and the phosphorus 3.9 mg. per 100 cc. The prothrombin time was normal. A bromsulfalein test revealed only 10 per cent re-

DR. MEANS: I should like to take Dr. Richardson on one point. I do not believe that lack of evidence of esophageal varices rules out splenic-vein occlusion. I had a famous case with numerous varices in the stomach that neither the radiologist or the endoscopist could find, but the surgeon found them all right.

CLINICAL DIAGNOSIS

Splenomegaly.

DR. RICHARDSON'S DIAGNOSIS

Malignant lymphoma of spleen.

ANATOMICAL DIAGNOSIS

Sarcoid of spleen.

FIGURE 1. Photomicrograph of Section of Spleen.

DR. RICHARDSON: The patient we are discussing today did not bleed.

DR. MEANS: I meant merely that perhaps you are taking a risk in ruling out splenic-vein occlusion just because no varices were demonstrated.

DR. CASTLEMAN: Dr. William Dameshek was called in to see this patient. His note is as follows:

This patient has a very large, hard spleen, associated with leukopenia and probably thrombopenia. There is no evidence of hemolytic anemia, cirrhosis of the liver or lymphatic leukemia. Nor does the blood or bone-marrow picture show any evidence of myelogenous leukemia or myeloid metaplasia. The hypochromic anemia may be coincidental and might respond to iron. Gaucher's disease appears to have been ruled out. This leaves us with either a chronic infectious splenomegaly (? type), a Boeck's sarcoid or a primary neoplasm of the spleen. I think that the spleen is bulky enough and causing sufficient symptoms to be removed.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The spleen was about three times its normal size and was removed. Scattered throughout the parenchyma were round, ill-defined nodules 1.0 to 1.5 cm. in diameter, many of which produced a vague nodularity on the surface. Microscopically these proved to be lesions characteristic of sarcoid (Fig. 1).

The patient has been followed in the Out Patient Department for two years and is feeling well.

DR. RICHARDSON: What about the nodes?

DR. CASTLEMAN: They probably would show sarcoid. None were ever removed.

A chest plate taken a month or so ago shows no change.

immature polychromatophilic cells, that would have raised the mean corpuscular volume. The sedimentation rate (0.65 mm.) was definitely elevated. The calcium (12.4 mg.) was high, and the phosphorus (3.9 mg.) was on the high side of normal. Why was the calcium high? My thought is that the calcium was high because there was a destructive bone lesion. The bone was being destroyed, and calcium was being excreted. The phosphatase level might have been interesting but not too helpful. There was plenty of free hydrochloric acid. The rest of the laboratory tests were negative. I have reluctantly ruled out benzol poisoning. Were there any varices?

DR. LAURENCE L. ROBBINS: No.

DR. RICHARDSON: I rule out thrombosis of the splenic vein on the basis of the clinical picture, the lack of esophageal varices and the lack of a history of bleeding. There is no evidence of cirrhosis of the liver unless the presence of a normal-sized liver and an enlarged spleen is suggestive.

Is there any evidence of bone tumor in these x-ray films?

DR. ROBBINS: Except for thinning of the cortex in the lower portions of the femurs, the bones are not abnormal.

DR. RICHARDSON: There was some talk about a bulge.

DR. ROBBINS: It is not particularly abnormal.

DR. RICHARDSON: What about the middle lobe of the right lung?

DR. ROBBINS: I should think that that was probably an old process, with perhaps some bronchiectasis.

DR. RICHARDSON: How about carcinoma?

DR. ROBBINS: I see no sign of a mass or anything that suggests complete collapse; it is only partial atelectasis.

DR. RICHARDSON: What I am coming down to as a diagnosis is a diffuse malignant process involving the bone marrow. In such cases one usually gets a leukocytosis instead of a leukopenia, but I have seen several cases in which there was this type of leukopenia. I would feel better about it if there were definite evidence of red-cell regeneration in the blood smear.

What kind of tumor was it? Could it have been a myeloma? The patient was young. The total protein was normal, although the globulin was perhaps slightly elevated — and the albumin was a little low. There is no other evidence of myeloma.

Lymphoma may give this picture; I have seen an identical case. That again brings up the question of the axillary lymph nodes. If this patient had enlarged nodes, I submit that an axillary biopsy should have been done before splenectomy.

DR. CASTLEMAN: Another observer said; "There is one large lymph node in the left axilla."

DR. RICHARDSON: If there were enlarged nodes in either axilla I should have taken them out before

doing a splenectomy. We cannot, however, say that question now.

What other tumors should be considered? Nephroma ought to be, but there is no real evidence for it. Carcinoma in the lung? There are no symptoms suggesting it. Carcinoma elsewhere, perhaps of the stomach or pancreas? It would seem one should consider carcinoma of the stomach. I shall assume that that was ruled out, although it is not mentioned. Was a gastrointestinal one done?

DR. CASTLEMAN: There is no record of it.

DR. RICHARDSON: Of all the possibilities I mentioned it seems to me that lymphoma is likely but I should not be surprised if it were carcinoma. Again, I say that it is with reluctance that I rule up the possibility that benzol played a part, but do so definitely.

DR. J. H. MEANS: Did you mention any conditions for which one would not do splenectomy?

DR. RICHARDSON: The reasons that I mention for doing a splenectomy are hemolytic and thrombopenic purpura, splenic-vein thrombosis possibly a large spleen that is mechanically difficult to carry around, usually a Gaucher's spleen.

DR. MEANS: I simply wanted to be sure that I had heard all your reasons because I came to grief standing on the same spot that you are standing on more than twenty-four hours ago in one of these exercises put on for the third-year class. Most of the students made the correct diagnosis, but I did not. On the features in that case was a big spleen. I do suppose that the same diagnosis holds in this case but it is an interesting point to bring up in differential diagnosis of any large spleen.

DR. RICHARDSON: I also mentioned malaria.

DR. MEANS: It was not malaria.

DR. CASTLEMAN: Why not tell him what it was?

DR. MEANS: Sarcoid.

DR. RICHARDSON: I never thought of it.

DR. MEANS: Neither did I — yesterday.

DR. RICHARDSON: I do not believe that this patient had sarcoid.

DR. MEANS: Are those shadows around the lung roots normal?

DR. ROBBINS: From the film alone I think they are vascular shadows. Of course one would have to see them fluoroscopically. If they are vascular they are within the limits of normal; if they are lymph nodes, they are prominent.

DR. RICHARDSON: I believe that this was the form of malignant tumor involving the bone marrow and that the likeliest guess is lymphoma.

DR. MEANS: Why did they take the spleen out?

DR. RICHARDSON: Why did they? I think it was a great mistake to have taken it out.

DR. MEANS: Was the pathologist consulted about this? Was a frozen section done?

DR. CASTLEMAN: No.

fe and opinion. Not all persons are above giving unfair and unjustified controversies between themselves and these impersonal groups, and many of them are clever enough to exploit the physician's active desire to please his clients. Any question of fitness or health that is raised becomes a crucial factor, and the doctor is called on to express his opinion, which if it is accepted becomes one of the determining factors in the outcome. If the doctor's judgment in these matters is favorably made and the usefulness and reputation of the profession may be greatly enhanced. If, on the other hand, judgments are carelessly expressed, they may become a means by which the profession can be undermined.

LYPHARMACY AND ANESTHESIA

THE scientific advances in anesthesia in the last decade have been truly spectacular, and largely because of them, surgeons have been able to operate successfully in many regions of the body previously inaccessible. Furthermore, the safety of their operative procedures has been increased by these new methods, provided they are expertly applied.

A development parallel with these tremendous advances but one that bothers many surgeons is the use of multiple sedatives in connection with anesthesia when such sedatives can hardly be expected to add materially to the success of the operation. A case in point concerns a healthy seventeen-year-old boy with early, uncomplicated appendicitis. For reasons that seemed adequate, the surgeon elected to do the operation under spinal anesthesia, although local anesthesia, any one of the anesthetic gases and oxygen or plain ether would have been perfectly satisfactory. Preoperatively, the patient was given by injection 1/6 gr. of morphine, 1/200 gr. of scopolamine and 2 gr. of Sodium Luminal. (One wonders how the anesthetist knows that 1/200 gr. of scopolamine is going to contribute to the success of this procedure. Would not 1/4 gr. or even 1/2 gr. of morphine achieve approximately the same effect? One also wonders, but not so seriously, whether the Sodium Luminal was necessary.) Spinal anesthesia, using a mixture of Pon-

tocaine and procaine, was given easily and with immediate effect, and the operation proceeded. After fifteen minutes the anesthetist was busily engaged in giving artificial respiration by compression of the rubber bag on an anesthesia machine and administering oxygen and carbon dioxide through the machine, and a nurse was giving hypodermic injections of Coramine. The artificial respiration proceeded with a minimum disturbance, except mental, to the surgeon, who completed the operation. At that time the patient was still asleep and breathing fairly well, with shallow respirations at a rate of 12 to 15 per minute; he could be roused but immediately dropped off to sleep again. Half an hour later the spinal anesthesia was still complete to a level just above the nipples. Convalescence was without event. (One wonders why, if the anesthetist had confidence in his spinal anesthesia, he had to give in addition a practically fatal combination of sedatives.)

Just because the well-trained anesthetist can keep a patient going under conditions such as these hardly makes one believe that this amount of preoperative medication is necessary. Furthermore, in similar cases of collapse, resuscitation is not always successful.

Many surgeons regularly use nurse anesthetists in their hospital practice, much to the chagrin of the anesthesiologists. Nurses, of course, are not always perfect anesthetists, but when well trained they do excellent work and, in general, heavy premedication is avoided, since the surgeon gives the orders.

A great advance in anesthesia might well be achieved by conscious efforts to simplify sedation in the average easy case, which comprises over 90 per cent of surgery. If the anesthetist could limit himself to a moderate dose of a single sedative, together with a suitable dose of atropine or some substance having the pharmacologic effect of atropine, followed by a single gas, vapor or injection, the vocation of anesthesia might be raised from its present position, where there is perhaps a little too much art and not enough science. Until this is done, the surgeon will have to protect his patient by consulting with the anesthesiologist in detail concerning each step of medication given before, during and after operation.

MEDICAL CERTIFICATION IN INDUSTRY

THE doctor has always regarded demands for written statements as burdensome. A Middlesex County fee table of one hundred years ago contains, among others, the following items:

For a visit in the village	\$.75
For a visit out of the village	1.00
For rising in the night and a visit, the night being considered as beginning at 10 o'clock and ending at sunrise	1.50-2.00
For a letter of advice.....	3.00

Were a corresponding value to be placed on the written statements the doctors of today are required to make most of them would prosper beyond their most optimistic dreams. In addition to reporting births, deaths, accidents and contagious and other diseases that come to their attention, the doctors are more and more called on to

express opinions concerning all sorts of controversial situations. They must decide if the student with a "cold" is to be excused from the examination he is not too well prepared to face, if patients are entitled to extra food, fuel, or other rations, if various types of work are or could be prejudicial to the health of certain people and if other people are completely convalescent and able to return to work or merely wish to extend a period of incapacity into a vacation. The decisions themselves always have to do with individuals, and on this account alone the circumstances are never twice alike. The manner in which the profession is meeting these responsibilities has recently been causing some concern. It is a department of professional activity in which character and integrity count, as they so often do, more than skill and knowledge, and it is also a department in which the profession is closely watched by those who would encroach upon it from without.

A letter from an industrial physician appears in the correspondence column of this issue of the *Journal*. This doctor is looking on both sides of the problem of medical certificates, and is suggesting that those who have to do with such certificates do likewise. The War Participation Committee of the Massachusetts Medical Society has recently had its attention called to the matter, and has prepared a blank form to cover medical certification for those seeking new employment in essential industries; a statement by the committee and a copy of the blank also appear in this issue of the *Journal*. The prestige of the medical profession is therefore being widely invoked in areas that not only have a direct bearing on its own reputation and future but that are now concerned with the survival of democracy itself.

The doctor has traditionally been called on to be an advocate of his patient. It has usually been the individual who has employed and paid him, and he has instinctively defended the patient against impersonal groups whose interests have been more highly socialized. Although the dignity of the individual is one of the tenets of democracy, such groups as insurance companies, benevolent societies and uncoerced industrial interests and enterprises are equally essential elements of our national structure, and they, too, have claims on medical

MASSACHUSETTS MEDICAL SOCIETY

WAR PARTICIPATION COMMITTEE

The accompanying certificate form (Fig. 1) has been adopted by the War Manpower Commission as the standard certificate for physicians to use when recommending change of employment for patients whose condition is or may be aggravated by continuance in their present jobs. The War Participation Committee has assisted in making this form as far as possible in order to save physicians' time and to give necessary information to the War Manpower Commission. The War Manpower Commission is of the opinion that physicians have been too easily prevailed on to issue certificates for change of employment. It is urged that physicians in giving these certificates exercise considerable care and discretion to make sure continuance in the present job is harmful to the patient.

The War Participation Committee has agreed to review the doctors' certificates, much in the same way that Dr.

MISCELLANY

ALVARENGA PRIZE

The College of Physicians of Philadelphia awarded the Alvarenga Prize on July 14, 1944, to Dr. Gervase J. Connor, of the Department of Surgery, Yale University School of Medicine, for an outstanding study entitled "Anterior Cerebellar Function: An analytical study in functional localization in the cerebellum in dog and monkey." This will be published in the December, 1944, issue of the *Transactions and Studies of the College of Physicians*.

The Alvarenga Prize was established by the will of Pedro Francisco da Costa Alvarenga, of Lisbon, Portugal, an associate fellow of the College of Physicians. "to be awarded annually by the College of Physicians on each anniversary of the death of the testator, July 14, 1883, to the author of the best memorial upon any branch of medicine which may be deemed worthy of the prize." The College usually makes this award for outstanding published work and invites the

WORKER	Last Name	First	Middle	UNITED STATES EMPLOYMENT SERVICE of the WAR MANPOWER COMMISSION MEDICAL CERTIFICATE
	Address		Social Security Account No.	

1. How long have you been treating the worker named above? _____

2. Diagnosis? _____

3. Would continuance of his present job be injurious to the worker? ☐ Yes ☐ No

(a) If "yes," why? _____

4. What sort of work will his condition permit? _____

Form _____ Date _____ Signature _____ (Attending Physician)

This certificate approved by the War Participation Committee of the Massachusetts Medical Society. It is subject to review by that committee.

FIGURE 1.

Ireland's committee reviews physicians' applications for rationations from the various ration boards.

In summary, the War Participation Committee has agreed to assist the War Manpower Commission and to co-operate with it fully. The War Manpower Commission understands that our committee is interested in seeing that physicians are fairly and courteously treated by the district offices of the commission. In other words, we stand ready to try to adjust any complaints physicians have against the War Manpower Commission or its branches, as well as to review the certificates sent to the Commission.

GUY L. RICHARDSON, *Chairman*

DEATH

SPARKS — Ernest E. Sparks, M.D., of Cochrane, died July 21. He was in his seventy-second year.

Dr. Sparks received his degree from the University of Vermont College of Medicine in 1902. He established the Cochrane civilian-defense medical center. He was a member of the American Medical Association.

His widow survives.

recipient to deliver an Alvarenga Lecture before the College. The College occasionally, as in this instance, awards the prize for an exceptionally important manuscript submitted in competition.

CORRESPONDENCE

INDUSTRIAL MEDICAL CERTIFICATION

To the Editor: Not the least of the time-consuming chores given to the physician in modern society is that of certifying to this or that concerning his patients. Because of the physician's role among his fellowmen, he emerged early in our social development as the logical one to certify birth, to certify insanity and to certify the occurrence of contagious disease. With increased emphasis on public-health measures the physician has the task of examining food handlers and candidates for marriage for the purpose of certifying that these are ostensibly free of certain specific infections. The physician is deemed to be the logical citizen, in a democratic way of life, to perform these necessary functions.

With the rapid growth of the insurance principle during recent years, there has been an increase in the need for medical

OBITUARY

SIDNEY CHASE GRAVES

1901-1944

Lieutenant Commander Sidney Chase Graves, Medical Corps, U.S.N.R., died on May 14, 1944, in the Pacific area. No details concerning this tragedy are yet known except that he had been well but a few days before and that death did not occur in action. Until his departure earlier this year for an assignment overseas, he had been for eighteen months on duty at the United States Naval Hospital, Chelsea, Massachusetts.

Dr. Graves was born on July 21, 1901, at London, England, the first child of Alice Myrick (Chase) Graves and the late Dr. William Phillips Graves. Thereafter his life centered about Boston and Nantucket. He went to Noble and Greenough School, Boston, thence to St. Paul's School, Concord, New Hampshire, and prepared for college at Milton Academy, Milton, Massachusetts.

From Harvard College he entered the Harvard Medical School, receiving his degree in 1929. He acquired his clinical training first at the Massachusetts General Hospital and then at the Free Hospital for Women. He became a member of the staff of the latter in 1932, and was appointed assistant in gynecology at the Harvard Medical School in 1933. He carried on his private practice in Boston. He was a member of the American Medical Association, the Massachusetts Medical Society, the Boston Medical Library, the New England Obstetrical and Gynecological Society and the Obstetrical Society of Boston, a fellow of the American College of Surgeons and a diplomate of the American Board of Obstetrics and Gynecology.

In 1934 he married Alice Driver Brown of Philadelphia and is survived by her, their three children, his mother, a brother and a sister.

From his early school days his even disposition, cheerfulness and good comradeship made him the center of an admiring group of friends. As he progressed through school and college and

SIDNEY CHASE GRAVES

maturity, his characteristics came more manifest, so that he was known and liked by an ever increasing number of both with and without medical profession. He excelled in many sports and developed considerable skill in sketching, his habitual "doodling" consisted of drawings of animals, faces and amusing caricatures.

In professional work Dr. Graves showed great earnestness and one might say super-consciousness for the welfare of his patients, private and public. Their devotion was his reward. The good results of his reliable surgery are constantly evident in the follow-up

of his patents. For example, patients with tumors of the breast had been his special assignment for ten years at the Free Hospital for Women and the survival in cancer of the breast are now unusually high.

The happiness of his family life was obvious to all who entered his home and was affirmed in a tribute recently written by his wife. He left their "whole world." Those who knew him will remember him for his outstanding integrity, kindness, humor, sociability and sportsmanship. He leaves his many associates with a feeling that he was robbed of many useful, happy years and that a true friend who can never be replaced has been taken from them.

J. L. N. and G. V.

rapidly rising with the increased expectancy of life that resulted from advances in both curative and preventive medicine. It is stated in the foreword that it will not be before one third of the population of the United States is over fifty years of age, and it has been estimated that in forty years there will be twice as many people living more than sixty-five years than there are now. It is in the realm of possibility that the activities of pediatricians will become less whereas those of geriatricians will become more, although this is not an immediate probability. Marriage rates are raising the birth rates in many communities. With the constant reduction in infectious diseases, the number of persons living into the later decades has greatly increased and therefore there will be relatively larger numbers of cases of circulatory diseases with varied manifestations.

The editor discusses geriatrics ably and at some length, makes clear the fact that there is a wide difference between the aged and the aging. This is a point that some physicians and many of the laity overlook. An aged individual is one who has lived a considerable number of years and has therefore become, in common parlance, an old person. But an old person may have fewer signs of aging than one many years younger. Aging begins in the early years, and consequently the physician should have the objective and subjective signs of aging constantly in mind. That is one of the greatest pleas for the routine, regularly spaced, physical examination. To treat only those ill with a definite disease is after all, rather poor medicine.

The reviewer has read several books on geriatric medicine, although all are more or less treatises on general medicine. The present volume adheres more closely to the subject of aging than do any of the others. The editor has selected fifty-four authorities who have written with clarity on many important topics concerning the aging and the aged. From excellent discussions of circulatory, lung, bone, genitourinary, blood and metabolic diseases, there is much sound advice to assist the general practitioner in adjusting the aging to the changing conditions of their

Handbook of Medical Library Practice, including Annual Bibliographical Guides to the Literature and History of Medical and Allied Sciences. Based on a preliminary manuscript by M. Irene Jones and compiled by a committee of the Medical Library Association. Edited by Janet Doe. cloth, 610 pp. Chicago: American Library Association, 1934. \$5.00.

This pioneer work is a distinct contribution to the literature of medical librarianship. In the preface the editor states that the objective of the book is to discuss "library procedures, methods and subjects commonly used and found in medical libraries but different from those found in general libraries." These objectives are met, and the book is a manual of procedure, as well as a reservoir of useful data, for medical librarians. Its faults, mostly of omission and inadequate treatment of subjects, do not detract from the value of the book to the physician. They are technical in character and only affect the professional library worker.

The work is divided into eight chapters, each written by a member of the Medical Library Association. The first chapter is a general one and has to do with the medical library, its development, its distribution and its administration. Appended to this chapter are items of importance: first a list of all medical libraries, situated anywhere in the world, having 100,000 or more volumes, and the second a description of medical libraries located outside North America. The other chapters are more technical and discuss subjects as periodical and book selection, cataloguing, subject headings, classification, pamphlets, pictures and microfilms. The final chapters in the manual deal with rare books and the history of medicine, as well as reference work, including an annotated list of reference books. The essay on rare books and the history of medicine might well have been published separately, since it is more comprehensive than what the librarian of the average medical library needs. The shorter presentation of the subject, more dogmatic in character and featuring certain primary objectives, would have served the purpose better than the extended treatment indulged in by the author. The same can be said about the chapter on reference work. Much of the material in this

section, however, is of particular interest to medical collectors, historians and bibliographers.

The outstanding weakness of the book is the failure of the various authors to discuss the fundamental values of the various procedures and methods treated. Nowhere can be found any reference to the relative importance of the various topics. The student of medical librarianship and the inexperienced library worker in the field of medicine is left adrift, since little attempt is made to suggest the best procedures to be followed in her daily work. Some subjects are presented, moreover, without indication why they are included.

The editing is well done, and the level of writing is uniform for a collected work, although there are places where the English could have been improved.

The Principles and Practice of Industrial Medicine. Edited by Fred J. Wampler, M.D. 8°, cloth, 579 pp., with 42 illustrations and 36 tables. Baltimore: The Williams and Wilkins Company, 1945. \$6.00.

This is a selected group of thirty-three dissertations, each of which deals with a specialized problem in industrial medicine. It is not an elementary textbook.

Occasionally one of the contributors takes the bit in his teeth and runs away with his subject matter in a way that may well overwhelm the casual seeker after simple advice. It is possible to spread confusion rather than enlightenment by means of studies that are too erudite and elaborate. As a minor illustration, Dr. Foulger, of the Haskell Laboratory of Industrial Toxicology, finds it necessary to interpret blood-pressure readings on chemical workers with the aid of the formula,

$$\ln S = -0.00339 (x^2 + y^2),$$

where $\ln S$ is the logarithm of S (the score) to the base of 10, x the deviation of the diastolic blood pressure from an established mean of 79 mm., and y that of the pulse pressure from an established mean of 44 mm. This formula may be valid, and the conclusions reached in his study are interesting and probably significant, but a simpler presentation and interpretation would be more generally valuable in a textbook.

Topics covered include a variety of intoxications, the effects of temperature and humidity, the eyes, the back, compensation, women in industry, fatigue, the physical examination, the lay-out of medical departments and so forth. It is sadly ironic that the author of the excellent chapter on the cause and prevention of accidents should have been accidentally killed before his contribution appeared in print.

This book is recommended for reference reading.

Plastic Surgery of the Breast and Abdominal Wall. By Max Thorek, M.D., LL.D. With an introduction by Rudolf Nissen, M.D., and a foreword by J. Eastman Sheehan, M.D. 4°, cloth, 446 pp., with 458 illustrations. Springfield, Illinois: Charles C Thomas, 1942. \$6.00.

The main subject of this book is the treatment of the hypertrophied breast. The author has made a sincere effort to describe the various operative procedures advocated by the many surgeons who have taken a special interest in this field of surgery. He analyzes quite extensively the different operative procedures that seem best suited to each particular problem. There is included a short chapter on reconstructive surgery of the abdominal wall, and also chapters on the anatomy, physiology and pathology of the hypertrophied breast.

The book is profusely illustrated with good diagrams and photographic illustrations, and it is one of the most complete monographs on the subject that has come to the reviewer's attention.

Convulsive Seizures: How to deal with them. By Tracy J. Putnam, M.D. 12°, cloth, 168 pp., with 12 illustrations. Philadelphia: J. B. Lippincott Company, 1943. \$2.00.

This is a brief manual covering various types of convulsive diseases, particularly written for patients and their families and friends. There is a good discussion on seizures and their causes, with additional data on diagnosis and the principles involved in treatment. Excellent advice is given

certification. Health and accident policies depend to an appreciable extent, it would seem, on the knowledge and integrity of practicing physicians for actuarial soundness and for fairness in the disbursement of funds. Industrial organizations have used the insurance principle to provide various benefits for employees. Compensation statutes require medical judgments as bases to support legal judgments. It has been necessary to use the doctor's statement in an equitable enforcement of rationing while the nation is at war. As one contemplates the intricacies of modern society it is apparent that the end is not yet!

It is doubtful that the physician could or should avoid his function in verifying the existence and character of illness for legitimate ends. There is reason to believe that he should, in some instances, insist on more adequate compensation for the time spent in preparing factually accurate certificates. There is likewise reason to believe that some certificates could be shortened or modified without loss of pertinent information. To avoid them altogether does not seem possible.

While the nation is at war and struggling to use its manpower with maximum effectiveness, the need to limit absenteeism in industry has focused attention on the character of medical certificates. (Babey, A. M. Absenteeism. *J. A. M. A.* 122:395, 1943.) The certificate should be a reliable guide in releasing prompt financial assistance for the ill worker. An instance has been reported (Current Comment. *J. A. M. A.* 122:812, 1943) wherein a physician "issued a certificate to the effect that a worker was sick with gastroenteritis and was unable to work for a period of six days in the month of May, whereas investigation developed the fact that the person who submitted the certificate actually was working in another establishment and was attempting to obtain pay from two sources by requesting sick leave with pay from one of them."

From personal experience, a request for disability was recently honored on the basis of a physician's certificate stating that the worker was unable to perform even light work at the plant. The worker accepted his disability payments and spent several weeks pushing a wheelbarrow filled with rocks to landscape his residence property! It is true that the family physician risks an irate patient if the physician objects to signing whatever statement the patient requests. On the other hand, one may ask what degree of confidence and respect will the patient have in his doctor if the latter, unwittingly or not, falls in with such connivance?

There is a pitfall in another direction. In view of the marked emphasis given by industry and its advisers to matters of industrial hygiene, the worker with any complaint is likely to blame his working environment. He has had his attention called to this possibility, and it is altogether reasonable that wishful thinking will lead him to indict fumes, gases, vapors, dusts and the like. Actually many unskilled workers have no idea what, if any, exposure they have at their jobs. Such a worker in the role of patient may influence his family doctor to certify to a most astounding and untenable diagnosis. It would seem well to urge that physicians protect themselves against these pitfalls by using confirmatory sources of information. The plant and the plant physician are sources for checking facts. Other sources are the state and federal divisions of industrial hygiene. The exceptionally complete library on industrial health and hazards of the Division of Occupational Hygiene, Department of Labor and Industries, 23 Joy Street, Boston, is available to New England physicians.

Much medical certification is done well. These comments are made not in a spirit of censure but rather by way of directing attention to a potential danger to the good name of the profession. If we must sign certificates, may they invariably be as unbiased and factual as is humanly possible. Our jobs must be scientifically done. Industry depends on the physician for an answer to medical problems. Regardless of their difficulty there is no one who is better qualified to get the answers than is the physician. Therefore it is essential that the approach to these matters should be sound and of the highest ethical quality, so that traditions that have cast so much luster on medicine in the past shall continue to flourish in the future.

LEMUEL C. MCGEE, M.D., Medical Director
Hercules Powder Company

Wilmington, Delaware

TEST FOR HYPERSENSITIVITY TO SULFONAMIDES

To the Editor: In the important and comprehensive editorial, "Cutaneous Sulfonamide Hypersensitization," the May 18 issue of the *Journal* nothing is said about demonstrating hypersensitization. As the problem of sulfonamide hypersensitization is much broader than its cutaneous aspect, and since some of the general manifestations may be serious, even fatal to the patient, it would be helpful to have a satisfactory test of a patient's sulfonamide sensitivity. For this the use of the drug as a patch or intradermal has been unsatisfactory, since negative tests are frequent in fact, almost the rule. There is a test, however, simple and that is claimed by its originator to be positive in the great majority of patients. This consists in injecting intradermally a small amount of serum from a patient who is taking a sulfonamide drug (Lewitich, W. An intradermal test for recognition of hypersensitivity to sulfonamide drugs. *Bull. Johns Hopkins Hosp.* 74:26, 1943) with the production of a wheal if the patient tested is sensitive to the sulfonamide that the patient from whom serum was taken had been receiving. The test is said by the author to be highly specific and reliable in the diagnosis of sulfonamide sensitivity. If this is confirmed, it will be extremely useful in the clinic in the differential diagnosis of conditions simulating sulfonamide-sensitivity effects, particularly as a precautionary measure to prevent giving again a sulfonamide to a patient who previously had been sensitized to it.

BOOK REVIEWS

Manual of Fractures: Treatment of external skeletal fixation. By C. M. Shaar, M.D.; and Frank P. Kreuz, Jr., M.D. cloth, 300 pp., with 148 illustrations. Philadelphia: W. B. Saunders Company, 1943. \$3.00.

This manual is the outgrowth of the authors' experience in the use of the Stader splint for 157 patients with various types of fractures. They give a concise and lucid description of the types of fractures best suited to this apparatus and the technique of its application, the postoperative care and hazards incident to its use. It has been found to be particularly useful in cases in which there are extensive burns or lacerations in the area of the fracture. This method of external skeletal fixation permits complete freedom of the joint which in turn lessens circulatory disturbances and muscle atrophy. Early use with rigid fixation also hastens union. In battle casualties its use facilitates early and evacuation from danger zones. The authors have observed no infection from the pins that hold the fragments. They advise gentle impaction with the turnbuckle bar after fracture is reduced. The treatment of different types of fractures, for example, that of the jaw, is taken up in detail. The apparatus, however, has been found most useful in fractures of the long bones. It has been used successfully in infected compound fractures and for fixation after grafts and arthrodesis. Chapters are appended on anesthesia in the treatment of fractures and on the roentgenographic aspects of fracture healing. The book is well illustrated with clear photographs.

Although this type of treatment of fractures will probably never become popular outside large hospitals, familiarity with such methods is desirable for all orthopedic and industrial surgeons. It is recommended as an interesting and useful book to those who are concerned with the treatment of fractures.

Geriatric Medicine: Diagnosis and management of diseases of the aging and in the aged. Edited by Edward J. Stieglitz, M.D. 8°, cloth. 887 pp., with 187 illustrations. Philadelphia and London: W. B. Saunders Company, 1943. \$1.50.

Geriatrics is becoming more and more a specialty of medicine since the number of older persons in this country is increasing.

A PRELUDE TO ETHER ANESTHESIA*

WILLIAM W. FORD, M.D.

BALTIMORE

In the thirteenth century Hugh of Lucca employed the *spongia somnifera* or sleeping sponge to relieve the pain of surgical operations. He is said to have introduced it in about 1250, a recent date in the history of anesthetics. Hugh's famous disciple, Teodoric (Teodorico Borgognoni, 1205-1296), Bishop of Cervia, described the sponge in his surgical treatise of 1266 and has sometimes been credited with its invention. References to it occur in the *Antidotarium* of Nicholas of Salerno, said to have been compiled in the eleventh century and one of the early medical books to be printed in the rich topography of Nicholas Jensen at Venice in 1471. Some authorities maintain that the prescription for the sponge was derived from older formulas for anodyne applications to the temples for insomnia and was used to produce a form of local anesthesia, citing references to its appearance in the works of Copho, Gaddesden and others. The celebrated remedy was prepared as follows:

Take opium and juice of unripe mulberry, of hyoscyamus, of the juice of the leaves of the mandragora, of the juice of the wood ivy, of the juice of forest mulberry, of the seeds of lettuce, of the seed of the burdock, which has large and round apples, and of the water hemlock, each one ounce; mix the whole of these together in a brazen vessel, and then place a new sponge, and let the whole boil, and as long as the sun on dog days, till it (the sponge) consumes it all, and let it be boiled away in it. As often as there is need of it, place this same sponge into warm water for one hour, and let it be applied to the nostrils till he who is to be operated on has fallen asleep; and in this state let the operation be performed. When it is finished, in order to rouse him, place another dipped in vinegar, frequently to his nose, or let the juice of the roots of fenigreek be squirted into his nostrils. Presently he awakes.¹

The use of a pain-nullifying agent, however, goes back to remote antiquity, for ever since man has suffered he has sought a "drowsy syrup" that might bring relief. Six thousand years ago and more, mandragora was employed by the Babylonians; there are references to soporifics in the Talmud; and in the twenty-first verse of the second chapter of *Genesis* we read: "And the Lord God caused a deep sleep

to fall upon Adam, and he slept: and he took one of his ribs and closed up the flesh instead thereof." Indian hemp (*Cannabis indica*) was in all probability the drug used by the Egyptians when performing surgical operations, and it is claimed that Helen gave this same drug to Ulysses in the incident narrated in the *Odyssey*. The mention of bhang occurs in the *Arabian Nights*, and there is evidence that the Orientals and the Greeks were quite familiar with the narcotic properties of opium, henbane, dewberry, lettuce and hemlock.

Inhaling the vapor of bhang for anesthetic purposes is mentioned in the writings of Hippocrates about 400 B.C. and later references to some form of narcosis are to be found in the works of Pliny, Dioscorides, Paulus Aegineta, Celsus and Avicenna. Pliny the Elder (23-79 A.D.) described mandragora and spoke of its soporific powers. It was also recommended as a surgical sleeping draught by Dioscorides† and Apuleius.

About 165 A.D. the Greek physician and philosopher Galen employed as an anesthetic for the removal of teeth an application of "pirethrin root and strong vinegar, from the action of which, the remaining teeth may be preserved by covering them with a layer of wax. At the expiration of an hour, the tooth becomes so loosened, as to be easily removed."²

Hao Tho, Chinese court physician at the beginning of the third century, operated on his patients while they were under the influence of a preparation of the hemp plant sometimes called "may-yo" and similar to the hashish of the Arabs.

The Peruvian Indians found a remedy in coca leaves, chewing them and swallowing the saliva. Persisting in the habit, they were apparently able to build up a considerable immunity to pain. In 1911, H. J. Mozans³ cited a modern instance of a *coquero* (one habitually chewing coca leaves) who was run over by a car. His foot was taken off in the accident, but he gave little or no evidence of suffering. The shamans or priests of old Peru also chewed

*This article forms the opening chapter of a forthcoming publication, *diagn. Thomas Green Morton and the Discovery of Surgical Anesthesia*, by the late William W. Ford, M.D., D.F.H., emeritus professor of otolaryngology, School of Hygiene and Public Health, Johns Hopkins University.

†Dioscorides was the first to refer to the use of mandragora wine as an anesthetic, and his formula was successfully tested by Richardson.²²

regarding various drugs, and this part of the book is distinctly valuable to physicians. The final chapter deals with legal problems connected with epilepsy, and there is an up-to-date reference to the current literature in an adequate bibliography.

This is a book that may be put in the hands of the more thoughtful patient and will be of value to a considerable proportion of practitioners who occasionally have to make decisions in regard to epilepsy.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Backache and Sciatic Neuritis: Back injuries—deformities—diseases—disabilities. By Philip Lewin, M.D., associate professor of bone and joint surgery, Northwestern University Medical School, attending orthopedic surgeon, Michael Reese Hospital and Cook County Hospital, professor of orthopedic surgery, Cook County Graduate School of Medicine, Chicago, and lieutenant colonel, Medical Corps, United States Army. With line drawings by Harold Laufman, M.D., instructor in surgery, Northwestern University Medical School, Chicago, and captain, Medical Corps, United States Army. 8°, cloth, 745 pp., with 235 illustrations. Philadelphia: Lea and Febiger, 1943. \$10.00.

This new book is a comprehensive treatise on diseases and injuries of the back. Emphasis is placed on diagnosis and treatment; the medicolegal, industrial and military aspects, are also discussed.

Pathology and Therapy of Rheumatic Fever. By Leopold Lichtwitz, M.D. With a foreword by William J. Maloney, M.D., LL.D., F.R.S. (Edin.), consulting neurologist to the City Hospital, New York City. Edited by Major William Chester, M.C. 8°, cloth, 211 pp., with 69 illustrations and 11 tables. New York: Grune and Stratton, 1944. \$4.75.

This monograph discusses rheumatic fever in all its acute and chronic aspects.

Internal Medicine in General Practice. By Robert P. McCombs, M.D., lieutenant, Medical Corps, United States Naval Reserve. 8°, cloth, 694 pp., with 114 illustrations. Philadelphia: W. B. Saunders Company, 1943. \$7.00.

This new manual on internal medicine is written especially for practitioners and students, and the field of diagnosis and treatment is especially emphasized. All the newer methods and mechanical aids in diagnosis have been included.

The Youngest of the Family: His care and Training. By Joseph Garland, M.D., physician to the Children's Medical Department, Massachusetts General Hospital, consulting pediatrician, Massachusetts Eye and Ear Infirmary, and instructor in pediatrics, Harvard Medical School. Revised edition. 12°, cloth, 182 pp., with 11 illustrations. Cambridge, Massachusetts: Harvard University Press, 1943. \$2.00.

This is a revision of a manual first published in 1932. It has been written to meet the exigencies of wartime. Because of the difficulty of obtaining many of the luxuries that once seemed indispensable in the care of the baby, instructions have been reduced to the simplest terms. Dr. Garland is a well-known pediatrician, and this revised edition should prove to be even more useful and valuable to the mother than the former edition.

Medical Genetics and Eugenics. Volume 2. By R. Ruggles Gates, Ph.D., D.Sc., LL.D., F.R.S., Marine Biological Laboratory, Woods Hole, Massachusetts; Laurence H. Snyder, B.S. M.S., Sc.D. professor of medical genetics, Ohio State University; and Earnest A. Hooton, Ph.D., Sc.D., Department of Anthropology, Harvard University. 8°, cloth, 60 pp., with 13 illustrations. Philadelphia: Woman's Medical College of Pennsylvania, 1943. \$1.00.

The present volume includes lectures given before a audience at the College of Physicians, Philadelphia. They have to do with the subject of heredity.

Fractures and Dislocations for Practitioners. By Edgar Geckeler, M.D. Third edition. 8°, cloth, 361 pp., with illustrations. Baltimore: The Williams and Wilkins Company, 1943. \$4.50.

This book was first published in 1937. The third edition has been revised to include sections on emergency and fracture wounds, particularly vital at the present time. New procedures have been simplified and considerable attention has been given to chemotherapy in the treatment of traumatic wounds. Débridement in the treatment of compound fractures is described so that the physician can perform the operation without delay if an experienced surgeon is not available. The manual is primarily written for the general practitioner who may be required to treat traumatic injuries in the absence of a competent surgeon.

Prelude to Sanity. By S. Greiner. 8°, cloth, 164 pp. Lauderdale, Florida: Master Publications, 1943. \$3.00.

It is the author's contention that, contrary to common psychiatric belief, schizophrenia does not constitute a clinical but a generic phenomenon.

Ship's Doctor. By Rufus W. Hooker, M.D. 8°, cloth, 272 pp. New York: Whittlesey House, 1943. \$2.50.

This is the autobiography of a physician who for four years followed the practice of medicine at sea, sailing a million miles in that time. The book is written in a narrative style and relates many experiences of Dr. Hooker in varying situations, ranging from the urgent call to SOS to conveying the wounded from Pearl Harbor and the Philippines.

The 1943 Year Book of Industrial and Orthopedic Surgery. Edited by Charles F. Painter, M.D., orthopedic surgeon, the Massachusetts Women's Hospital and Beth Israel Hospital, Boston. 12°, cloth, 440 pp., with 306 illustrations. Chicago: The Year Book Publishers, 1943. \$3.00.

This volume provides a summary of progress for the year in the fields of orthopedic surgery and of industrial medicine and surgery. The material is well selected and printed in excellent type on a good grade of paper.

Nascent Endocrine Therapy. By John F. Ritter, M.D. 8°, cloth, 317 pp. Caldwell, Idaho: The Caxton Printers, Limited, 1940. \$5.00.

In this book the author describes his treatment of essential hypertension.

Medical Advice from a Backblock Hospital. By G. M. Smith, M.B., Ch. B., F.R.C.S.E. With articles and notes by A. Bedgood, Vernon Brown, F. Cook, L. M. Copley, N. Gilchrist, E. Harwood, A. Kernihan, W. H. Kirkpatrick, E. Tait, H. Maxwell and Barbara Orr. Second edition. 8°, paper, 96 pp. Wellington, New Zealand: Progressive Publishing Society, 1943. 1 shilling.

This work is a description and an explanation of the Hologanga Co-operative Clinic Medical Service, located in New Zealand. The first edition was published in March, 1942, and the second edition affords the author an opportunity to reply to the criticism and to answer his critics. The principal part of the pamphlet is a manual of domestic medicine to which are added replies to critics on social medicine among the Maoris.

Child Welfare Handbook: A guide to health and social service. Edited by Beatrice S. Stone. 8°, paper, 58 pp. Boston: Publications Committee of the Massachusetts Child Council, Incorporated, 1943. 25 cents.

This pamphlet is fundamentally a directory of all organizations in Massachusetts having to do with child welfare. It is an essential reference source of information concerning the subject.

the chemistry of the various substances called "ether" was not always well understood. Accurate directions for making it were probably first given in the *Pharmacopoeia* published by the Massachusetts Medical Society in 1808 and prepared for the Society by Dr. Jacob Bigelow and Dr. James Jackson. But it was not until 1830 that methods of preparing ether were given *in extenso* and became widely available in America. In that year the *Pharmacopoeia of the United States* gave a complete account of the preparation of its listed drugs, and the chemistry of the different ethers was further cleared up when Daniel Smith¹² published a comprehensive paper in the *Journal of the Philadelphia College of Pharmacy* in 1832–1833. He described over fourteen chemical compounds called "ether," among them a variety of chloric ether (later known as chloroform), sulfuric ether and oil of wine.*

Additional references to ether appeared in Pereira's widely read *Elements of Materia Medica*,¹³ published in 1839—three years before the first operation under ether narcosis was to be performed by the young country practitioner at Jefferson, Georgia. Earlier and painstaking investigation, which Sir Humphry Davy styled "the pathetic quest for oxygen," terminated brilliantly with the discovery of several gases in the second half of the eighteenth century, and the Chemical Age was firmly established. The discovery of carbon dioxide by the Scottish chemist Joseph Black, in 1757, was followed by the discovery within the next eighteen years of hydrogen by Cavendish, nitrogen by Rutherford and oxygen by Priestley, the Swedish investigator Scheele and Lavoisier. Preceding his discovery of "dephlogisticated air," as he called oxygen in accordance with Stahl's doctrine,† Joseph Priestley had discovered nitrous oxide in 1772. In 1775 oxygen, which John Mayow had come so near discovering in the seventeenth century, was once more isolated and clearly defined by Antoine-Laurent Lavoisier, and the phlogistic doctrine, long confusing and hampering chemists, was overthrown by this distinguished worker.

Medical practice was soon influenced by the various discoveries, particularly that of oxygen, physicians were carried away by their imaginations to the extent of attributing diseases either to lack or excess of oxygen, or to some fine-spun modifications of this theory," as Garrison¹⁴ has said.

A pioneer in the use of gases in medicine and contributing indirectly to the advancement of

anesthesia was Dr. Thomas Beddoes, who founded a Pneumatic Institute at Clifton Hotwells near Bristol, England, in 1798. Here bodily and mental ills were treated by the inhalation of gases, and a sort of inhalation therapy developed and became extremely popular for a time.

The noted James Watt, in addition to collaborating with Beddoes in the publication of *Factitious Airs*, which related to the pneumatic methods, had constructed the apparatus at the institute, and Humphry Davy was Beddoes's chief assistant. In 1799 Davy¹⁵ published the results of his experiments with nitrous oxide gas, which he had discovered to be an anesthetic while inhaling it to relieve an aching tooth. A little later he gave a series of popular lectures, followed by demonstrations of nitrous oxide, calling it "laughing gas." In 1800 further demonstrations of the gas were given by William Allen, the lecturer on chemistry at Guy's Hospital in London.

A man of wide interests and extensive acquaintance, Dr. Beddoes's work at Clifton, which the youthful Davy described as "the loveliest spot in the world," attracted the attention of Erasmus Darwin, Thomas Wedgewood, Wordsworth, Coleridge, Southey and many others. Both Southey and Coleridge were among the first to inhale nitrous oxide after Davy's successful experiments, Coleridge writing a glowing account of his sensations. But after a few years the initial enthusiasm began to decline, medical opinion altered, and there were many rumors concerning patients who had been troubled with dizziness, lowered pulse and other unfavorable symptoms as a result of pneumatic methods. Several years before his death in 1808, Beddoes, disillusioned, his theories having encountered strong opposition on all sides, converted the institute into a hospital where the usual forms of treatment were adopted, Humphry Davy meanwhile dropping his own investigation of nitrous oxide gas to win many laurels in other fields.

In about 1784 James Moore revived anesthesia by compression. The principal nerves and vessels of the neck were compressed to produce local anesthesia or insensibility. But after some fatal results this practice was soon discontinued.

Shortly before the French Revolution, Frederick Anton Mesmer employed animal magnetism or "magnetic emanations" to produce insensibility to pain, his armamentarium including a lilac robe (which he always wore at his hypnotic séances), a harmonica, a magnetized wand and later the *baquet* or wooden tub, containing a series of bottles "charged with animal magnetism." Discredited in Vienna, Mesmer had settled in Paris in 1786. Here he was also rebuffed, but not before he had enjoyed a period of extraordinary success and prosperity, being acclaimed by members of the French Court and other celebrities. He failed in all his efforts to obtain scientific recognition, however, and at the outbreak

*Until the early 1850's ether was produced by the open fire, intermittent distillation method. This method was not only dangerous from the standpoint of fire hazard but involved the problem of selecting the correct proportion of the distillate to be employed for anesthesia. In 1856 an important contribution was made by Edward R. Squibb, then assistant director at the United States Naval Laboratory. Experienced in the manufacture of ether for some years past, he had developed a method of making the drug by continuous steam heat through lead coils, and in an article entitled "Apparatus for the preparation of ether by steam," published in the September, 1856, issue of the *American Journal of Pharmacy*, gave a detailed report of his new, and revolutionary method.

†The principle of inflammability supposedly existing in combustible bodies. The theory was that when matter burns it gives off a hypothetical substance, "phlogiston."

the leaves and applied the spittle to the wounds of their surgical patients. From the active principle contained in the leaves of *Erythroxylon coca* the alkaloid cocaine was to be produced in the nineteenth century.

Compression effected by mechanical means and continued a sufficient length of time to cause numbness in that part of the body to be operated on, was first practiced by the Egyptians and has been reintroduced by surgeons at different periods.

Following Theodoric, Guy de Chauliac (1300-1368), the great surgeon of the Middle Ages, is the only medical historian of importance to mention or describe the "sleeping sponge."⁴ In the medical writings of the period there are other references to the use of narcotics, chiefly opium, but at the same time the danger of asphyxia, congestions and even death as a result was emphasized. Unquestionably this did much to retard the practice of any extensive drugging in the treatment of patients. It is stated, however, that criminals of the fourteenth, fifteenth and sixteenth centuries, when facing execution or prolonged forms of torture, frequently had some narcotic dose administered by a compassionate jailer.

More than one reference to anesthesia has occurred in literature while the actual use of it was declining. Boccaccio, Shakespeare, Marlowe and Middleton all mention narcotics. The well-worn quotation:

I'll imitate the pities of old surgeons
To this lost limb, who, ere they show their art,
Cast one asleep, then cut the diseased part.

taken from Middleton's *Women Beware Women*, furnishes perhaps the best example.

* * *

In the middle of the sixteenth century the skillful hands of Ambroise Paré (1510-1590) lessened the supreme torments of surgery by the application of ligatures and simple dressings in place of boiling oil or cauterization with red-hot irons—the usual treatment for wounds and the stumps of amputated limbs. Following on his chance discovery, as military surgeon before Turin, that gunshot wounds were not "poisonous," Paré opposed the doctrines of his contemporaries and conducted a spirited campaign for the adoption of soothing methods in wound treatment, but the use of the sleeping potion or "sponge" was apparently unknown to him. And in the seventeenth century, during which medical history was enriched by an imposing catalogue of names beginning with that of William Harvey (1578-1657) and the dignity of medicine was so ably portrayed in the canvases of some of the great Dutch painters, including the "Anatomies" of Adriaen Backer and Johan Van Neck, the employment of any pain-relieving agent was forgotten or almost wholly disregarded.

In 1730 the chemist Frobenius described sulfuric ether in the *Philosophical Transactions* of the Royal Society at London,⁵ designating it "spiritus vitæ æthereus." The preparation of ether by the action of sulfuric acid on alcohol had been known since the thirteenth century. Raymond Lully (1235-1315), philosopher and alchemist of prominence, was apparently the first to discover it. The drug was then referred to as "sweet vitriol" or "*oleum dulce vitrioli*." In 1540 ether was rediscovered and its properties described by Valerius Cordus (1515-1544), a young apothecary and a student under Paracelsus, who had once happened on ether himself, it is stated, trying the effects of it on chickens. More than a century later "sweet vitriol" was also mentioned by Sir Isaac Newton, Godfrey and Boyle.

During the eighteenth century the medicinal employment of ether was alluded to by such prominent physicians as Hoffmann (Hoffmann's anodyne), Cullen, Alston, Lewis and the Monros. In 1795 Richard Pearson recommended the inhalation of ether in treating phthisis or pneumonia, directing that the patient "pour one or two teaspoonfuls of pure vitriolic ether, or ether impregnated with icuta . . . into a teacup or wineglass and inhale the same three, four or five times a day."⁶ Several communications from Pearson are included in *Facitious Airs*,⁷ the essays of James Watt and Dr. Beddoes, published at Bristol, England, in 1795, and printed in the *Annals of Medicine* the following year. One of Pearson's communications refers to a letter from Dr. Thornton describing the inhalation of sulfuric ether in treating catarrh, where the patient, much relieved, fell into a deep slumber.

In 1815 Nysten, in a dictionary of medical sciences,⁸ spoke of ether as familiarly known for mitigating the pains of colic and other minor ills, and described apparatus or methods for inhaling it.

Michael Faraday, in 1818, published the following in the *Quarterly Journal of Science and the Arts*: "When the vapour of ether is mixed with common air and inhaled, it produces effects very similar to those occasioned by nitrous oxide. By the incautious breathing of ether vapour, a man was thrown into a lethargic condition which, with a few interruptions, lasted for thirty hours."

Dr. John Collins Warren spoke of resorting to the inhalation of ether as early as 1805 in order to relieve a patient dying of pulmonary tuberculosis.⁹ In 1832 Daniel Drake listed ether among the remedies to be taken internally for cholera.¹⁰ Franklin Bache, in 1833, collaborating in the preparation of the massive *United States Dispensatory* (first edition) gave a description of the chemical properties of the drug and referred to its medicinal uses.¹¹ Other American authorities mentioning ether during the decade of 1822-1832 included Godman, Mitchell and Professor Samuel Jackson. In considering the early references, however, it should be remembered

of the Revolution left Paris and lived in retirement for some years before his death, which occurred in 1815. But mesmerism, invading surgery in the nineteenth century, was to have such disciples as Braid, the outstanding pioneer of scientific hypnosis and originator of "Braidism," Elliotson and Esdaile. John Elliotson, a friend of Thackeray's, to whom the novelist dedicated his *Pendennis*, performed the first surgical operations in about 1840 on patients who had been hypnotized, claiming success. In 1843 he published a pamphlet, *Numerous Cases of Surgical Operations without Pain in the Mesmeric State*, which soon provoked dispute and led to his resignation as president of the Royal Medical and Chirurgical Society, as a professor of practice in the University of London and to his withdrawal from other offices. James Esdaile fared much better in the Indian Medical Service, and his operative work among the Hindus, which he began in 1845, attracted attention for some time, although the general verdict of the Western scientific world was distinctly unfavorable.

In 1808, Frederick Wilhelm Sertürner, a German apothecary, extracted morphine from crude opium. Publishing the results of long experiment, he received honorary degrees from the Universities of Paris, St. Petersburg and Berlin, among others. In 1831, he was awarded a Montyon prize of 2000 francs for his discovery. Nevertheless, the conquest of pain in surgery was generally regarded as a remote possibility at this time, and Sertürner, becoming embittered by certain manifestations of professional jealousy, engaged at length in the study and improvement of firearms.

Severino had produced local anesthesia with snow and ice in 1640. At the battle of Eylau in February, 1807, Napoleon's surgeon-in-chief, Dominique Jean Larrey, who on occasion performed two hundred amputations in twenty-four hours, observed that wounded men half frozen from the cold experienced little pain when operated on. Larrey's discovery led to refrigeration anesthesia, which was shown to have so many undesirable features that it was soon abandoned. Later it was reintroduced.

In 1824 a young English physician, Henry Hill Hickman, performed a number of operations on animals, using carbon dioxide as an anesthetic. Hickman, it is said, first became interested in gases as a result of practicing for a time at Shiffnal, the birthplace of Dr. Beddoes. Returning to his native Ludlow in Shropshire, Hickman studied the work of Priestley, Davy and Faraday and conducted a series of experiments. Encouraged by the apparent success of his efforts, he went on to employ nitrous oxide when performing various operations on dogs, chickens and cats, and at about this time attempted to interest the Royal Society in his work. Writing to a friend, T. A. Knight, a botanist and member of the society, he gave a detailed report of his experiments, making the request that it be sub-

mitted to the proper authorities. But Knight, although at once interesting himself in the matter, was unable to help him. Both Sir Humphry Davy, then president of the Royal Society, and Michael Faraday were engaged in other absorbing problems, and Hickman's report was never even read before a committee.

Hickman, entertaining high hopes of being able to operate on his own patients under anesthesia, was not ready to accept defeat and printed a public letter. When this was ignored he presented a memorial to King Charles X of France in 1828, containing the statement: "It appears demonstrable that the hitherto most agonizing dangerous and delicate surgical operations may now be performed, with perfect safety, and exemption from pain, on bruta animals in a state of suspended animation" But the French were not interested after the Royal Academy of Medicine, with the possible exception of Dominique Larrey, failed to find anything of importance in Hickman's claims. Doomed to disappointment, Hickman could only continue his work alone. He died in 1830 at the age of twenty-nine, and more than a decade was to pass before the discovery of surgical anesthesia.

Samuel Guthrie, of Sackett's Harbor, New York, made chloroform in 1831 by distilling alcohol with chlorinated lime. In that same year chloroform was discovered independently by Soubeiran¹⁷ in France, and Leibig¹⁸ in Germany. It was first used medicinally as a solution of chloric ether, and regarded as a particularly pleasant intoxicant. "During the last six months, a great number of persons have drunk of the solution . . . in my laboratory," Guthrie wrote, "not only freely but frequently to the point of intoxication . . . it has appeared to be singularly grateful, both to the palate and stomach, producing promptly a lively flow of animal spirits, and consequent loquacity; and leaving, after its operation, little of that depression consequent to the use of ardent spirits."¹⁹ In July, 1832, Daniel Smith, in classifying it among the ethers, observed: "The action of this ether on the living system is interesting and may hereafter render it an object of importance in commerce. Its flavor is delicious, and its intoxicating qualities equal to or surpassing those of alcohol."¹² Jean-Baptiste Dumas analyzed the solution in 1834 and gave it the name of chloroform, but its anesthetic qualities were not to be recognized until James Y. Simpson introduced it in childbirth some thirteen years later.

The picture, then, was not too bright. Surgical technics had improved since Paré, but human suffering was much the same. "A humiliating spectacle of the futility of science," John Hunter declared in the eighteenth century, and in the nineteenth Charles Darwin, writing his *Autobiographical Recollections*, recorded: "I also attended on two occasions the operating theatre in the hospital at Edinburgh and saw two very bad operations, one on a child.

e instructor. In the last analysis the material is ing presented to the student for purposes of instruction, and if he gains nothing from it, it should be revised to the point where it is beneficial.

The next question is whether it is better to use typewritten material or that turned out by any of the semimechanical lettering guides now in use. Typewritten material is the poorest of all from the standpoint of projection on a screen because of the plain body of the characters and the ragged appearance of the type when enlarged on the screen. It is generally agreed that semimechanically lettered charts of tabulated material are much more easily read and present a much neater appearance. This is particularly important when material is to be presented at a medical meeting, because every speaker falls in the estimation of his audience if his lantern slides are poor.

When tabulated material is being prepared, more pleasing results will be gained if it is kept within proportions of the lantern slide, which is $3\frac{1}{4}$ by 4 inches. This produces the maximum size of letters on the screen for any given projection distance and ensures a minimum of wasted space.

Another subject of controversy has frequently been the number of x-ray films or ordinary photographs that can be reproduced on a single lantern slide. Here again, it depends somewhat on the subject whether more than two images can be placed on one slide and projected so that the entire audience can see the subject plainly. A single tiny spot on a chest plate reproduced in four films on one lantern slide is apt to show up poorly because of the small size of the projected image. On the other hand, details that are relatively large in a single film or photograph show up well in a number of images on one slide.

Motion pictures have come into great prominence during the last few years as a medium of teaching medicine. An enormous number of films have been made by many persons — some of them good and some worthless, not from the standpoint of poor photography but from that of scene length and continuity. This defect is caused by lack of preparation before the film is made. A good teaching film must be prepared in the form of a scenario or scene schedule. If it is an operative film, the photographer should see a similar operation before attempting to produce a motion picture, in order that he may know what to expect during the actual making of the film.

It is not infrequent that some interesting material is discovered during an operation and someone conceives the idea of having a motion picture made of it on the spur of the moment. Often after the film is made, it is never used and is forgotten, but if used by someone, it is found that the film was started in the middle of the operation. There is no preliminary matter to explain what went on before and no follow-up to show the end result. In general,

films of this nature have absolutely no reason for being.

The preparation of a properly made medical teaching film begins with a conference between the instructor and the photographer, at which time a rough outline of what should be covered is laid out, and from this a taking schedule or scenario is made up. At that time the photographer and the instructor find out what each will need for material and what material will be required for each scene. They decide how much should be included in the scene, and whether to employ a close-up view or a long shot, and attend to the thousand and one details that must be settled before a single foot of film is run through the camera. In this way a minimum of material is wasted, the work proceeds more rapidly, and the end result is usually satisfactory and does not require additional scenes to be supplied at a later date.

When using color film in motion pictures, it is desirable that all the film be processed at one time, because there are minor variations in color in different processing solutions. For this reason the scene schedule should be complete before the film is processed. The use of color in motion pictures has been greatly accelerated in the last three years. Many medical subjects are far more realistic when done in color. Others can of course be done in black and white, but color is here to stay and wider use should be made of it whenever possible.

There has been much controversy over the length of a teaching film. Some experiences lead one to believe that a medical student cannot possibly stay awake through a film that lasts over ten minutes. Actually, if a film is presented in an interesting manner, there is little difficulty in keeping his attention. Thirty to forty minutes of running time seems to be the average period during which his interest can be held. Students frequently criticize motion pictures showing treatment because the latter is made to appear much too easy or simple. One of the reasons for this is that the average motion picture of treatment procedure shows only the high lights, omitting the minor motions and the preparation for treatment. On the other hand, if a film is to show all the preparation, treatment and after-care, great pains must be taken so that it will not drag, for the student frequently loses interest if this occurs.

Four or five years ago, a noted pediatrician and a clinical photographer successfully worked out a method of presentation of motion pictures in conjunction with one of the former's lectures. The projection material consisted of a series of short films pertinent to the subject of the lecture, which were connected by short pieces of blank film. The running of each section required from 30 to 60 seconds. The instructor proceeded with his lecture, and at certain points he paused and a section of the film was shown. As soon as this particular section

AIDS TO VISUAL EDUCATION IN MEDICINE

F. R. HARDING*

BOSTON

THERE is greater need for a wide use of visual aids in teaching medical subjects at this time than there has been for many years. With such a large number of instructors now in the armed forces, it becomes necessary to use every possible aid in teaching.

Visual aids may take several forms. Large charts, photographs, lantern slides and motion pictures are all most necessary. Each of these forms has its own particular function to fulfill. It should be borne in mind that a photograph can tell a student more than can many pages of printed matter. Tests conducted by the United States Bureau of Education¹ have definitely proved that students learn more in a shorter time through pictures than they do from printed matter or the spoken word. With the greatly concentrated medical teaching program now in progress, it seems necessary to use all these visual aids to the largest possible extent.

Large charts are frequently advantageous in presenting material in tabulated form. They may be hand-lettered on large sheets of paper and placed on an easel before the students. These charts are of particular value if the students are required to copy the material in notebooks. The chart is usually left on the easel for a length of time sufficient to allow the slowest student to copy the material. Sufficient classroom lights should be on to enable the students to see their notebooks. Tests should be conducted to make sure that too much material is not placed on the charts. The material should be condensed as much as possible, bearing in mind that students absorb more readily two charts with ten lines on each than one chart with twenty lines. All charts must be so constructed that they can be easily read by students in the back rows.

Photographs can frequently be used to their best advantage in bedside teaching by showing the patient before and after treatment. They may also be enlarged and used as an exhibit. An exhibit of this kind is of no value unless a printed description accompanies each photograph and the students are given sufficient time in which to study it thoroughly. A place for a permanent exhibit can sometimes be arranged, with great benefit to the students.

The primary use of photographs is in the clinical record. It must always be borne in mind that the medical student rarely has a chance to see more than a small percentage of the patients both before and after they have been treated. The more complete the photographic record, the more valuable it will be for the purpose of study.

*Director of photography, Children's Hospital.

Lantern slides are invaluable for covering a complete topic. They have been used and misused for many years, and there is a great deal of controversy over the best method of displaying them. It is generally understood that about forty lantern slides an hour is the maximum that can be taken in by students. This allows an average of somewhat over a minute for discussion of each lantern slide. If it is thought that more slides than this must be used, it is suggested that the slides be re-examined with a view toward discarding those that are of least importance. If more than forty lantern slides an hour are projected, the effect is most disconcerting to the student, sometimes to such a point that he gains nothing from the material. Many slides contain tabulated material — sometimes large quantities of it. From the student's point of view, this is undesirable, for two reasons. First, he is discouraged by a large mass of material and frequently does not bother to read it all. Second, large masses of printed material reproduced on a lantern slide are extremely small even when projected, and if the lecture room is large, those at the rear of the room may be unable to read what is on the screen. Some years ago the members of the Mayo Clinic² after considerable study reached the conclusion that for general use under varying conditions, fifteen typed lines of tabulated material is the maximum that should appear on a slide. This amount can be somewhat increased, probably to twenty lines, if the material is made with lettering guides instead of on a typewriter. Because of unknown projection conditions, such as the distance from the projector to the screen and the size of the screen in relation to that of the room, lantern slides must be so made that they will give the desired message regardless of local conditions.

Sometimes large quantities of material are necessarily projected on the screen to show the pattern or course of some particular subject; this does no harm. At other times a large amount of material is prepared in the form of a lantern slide as a guide to the lecturer. This is rather unfair to the student because the material must be read by the instructor and could be included in his text. If typed tabulated material is divided into sections with India ink, it becomes much easier to follow on the screen. Frequently masses of material can be broken down into more than one lantern slide with great benefit to the student. The instructor often loses sight of the fact that if his material is not good or is poorly presented, the student gains little or nothing from the time and effort that have been devoted to it by

material will undoubtedly be projected and that it must be readable from the back of the hall.

For deciding on the proper size of screen, a good rule is that the width of the screen should be one sixth of the distance from the screen to the back row of seats. This rule is adequate, and works well when the first row of seats is ten feet or more from the screen. If the screen must be nearer the audience than this, it should be slightly smaller so that the projected image will not appear excessively magnified or distorted.

The projection screen should be chosen with regard to the shape of the auditorium. If most of the seats come within a viewing angle of 25° , as is true in the average lecture hall, a beaded screen will produce the greatest brightness. If the room has small depth but great width, a white screen will produce the best brightness for the majority of the audience. In the latter case vision from an angle of greater than 45° is sure to be distorted.

Pertinent data covering the focal-length of the lens, the distance from the lens to the screen and the size of the image are given in Figure 1. These

are based on a 3-inch opening in the slide. Since some slides utilize the entire effective width ($3\frac{3}{4}$ inches), the screen must be large enough to care for these slides also.

Projection screens should be protected from dust when not in use, and the lens mirrors and condensers should be kept spotlessly clean. When projectors equipped with Mazda lamps are used, old, blackened lamps are a prolific cause of poor illumination.

MULTIPLE EXTRAGENITAL GIANT CHANCRES*

Report of a Case.

WALTER F. LEVER, M.D.†

BOSTON

RECENTLY a patient with three large ulcerated extragenital chancres was seen at the Massachusetts General Hospital. Two chancres were located on the chin and one in the left inguinal region. A report of this case is submitted not only because of the unusual size of the chancres but also in order to emphasize the importance of considering a diagnosis of primary syphilis in dealing with ulcerated lesions of the skin.

CASE REPORT

A 28-year-old woman first noticed two small papular lesions, one on each side of the chin, on June 10, 1943. One week later, a similar papule developed in the left groin. The three lesions gradually increased in size and became slightly raised and covered with heavy, dark-brown crusts. Two weeks after onset, the right submaxillary lymph nodes became enlarged and so painful that the patient lost much sleep. The lesions themselves were neither painful nor tender.

On July 10, one month after onset, the patient was seen at the Massachusetts General Hospital. The lesions were covered with heavy, oyster shell-like crusts. Each of those on the chin showed, after removal of the crusts, a central ulceration surrounded by a bright-red, slightly raised margin (Fig. 1). The larger lesion, on the right side, measured 3.5 by 4.4 cm., and its central ulceration 1.6 by 2.8 cm. The

lesion on the left side measured 1.5 by 1.5 cm., and its central ulceration 0.5 by 0.6 cm. Palpation of the lesions revealed distinct induration of the margins as well as of the bases of the ulcers. Both showed a granulating base covered by a grayish-green membrane of necrotic tissue. The edges of the ulcers were slightly serpiginous and overhanging. There was profuse secretion of a clear, serous exudate in amounts large enough to cause occasional dripping from the lesions. The right submaxillary lymph nodes showed moderate enlargement and considerable tenderness. The left submaxillary, anterior cervical, submental and hyoid lymph nodes were slightly enlarged but not tender.

The lesion in the left inguinal region presented, after removal of the overlying crust, a narrow, cleftlike central ulceration surrounded by a wide area of erosion (Fig. 2). The entire lesion measured 5.5 by 1.5 cm., and the ulcer 1.7 by 0.2 cm. There were the same induration and the same serous secretion as those observed with the lesions of the chin. The left inguinal lymph nodes were moderately enlarged but not tender.

Aside from the three ulcers the skin was normal. There were no lesions on the visible mucous membranes, and on examination by speculum the vaginal mucosa and cervix were found to be free from lesions.

Darkfield examination revealed in each of the three lesions numerous spirochetes whose characteristics conformed to those of *Treponema pallidum*. Aerobic and anaerobic cultures showed only a few colonies of *Staphylococcus albus*. Reactions to both a Hinton and a Wassermann test were positive. Intracutaneous tests for chancroid and lymphopathia venereum were negative.

To avoid a Herxheimer reaction, arsenicals were at first withheld and treatment was inaugurated with five injections of water-soluble bismuth sodium tartrate, 0.2 gm. being given on alternate days. On the day following the first injection, a generalized macular eruption appeared on the skin. A diagnosis of secondary syphilis was made.

had been run through the projector, the latter was stopped and the lecture proceeded until the next of what were called "punch points" was presented. In this way the student was able to see the actual characteristics of the subject under discussion at the time when the symptoms and treatment were fresh in his mind.

If the instructor depends on living patients to illustrate his lecture, he frequently finds that, when the lecture period comes around, he has no patient with the particular feature that he is going to discuss. By using motion pictures the subject is always there, rolled on a little reel and sealed in a tin. A much wider use of motion pictures could be made

of a patient that could not be recorded photographically was the plantar aspect of the feet when bearing weight. It is now possible to do this quite successfully.⁶ The required apparatus is simple and easily constructed. It opens a new field to the orthopedist for the photographic and visual record of patients with foot deformities.

Photography in the operating room is of great value in visual education, particularly when teaching time is so precious and students have little opportunity to observe operations. The photographic problems involved do not properly concern the instructor, and they vary in every hospital. Most of these have been solved, and a much greater

in teaching medical subjects. It is claimed that they are too expensive, but if the medical student gets more instruction through the judicious use of motion pictures than from stills, the expense involved is immaterial. If a lecture is not worth the outlay of a sum of money to make it of greater value to the student, it is evidently of no great importance.

At the Children's Hospital a number of aids to better visual education have been developed. Some years ago a screen grid was superimposed on certain orthopedic photographs.^{3, 4} With the aid of this grid it is possible to see the deviation from normal of a spine, the tilt of the head in torticollis, the bowing of the legs, asymmetry of the face and so forth. In short, the grid shows up any deviation from the normal. It has had wide use since it was first constructed. Also introduced is so-called "phantom photography," which is a controlled method of double exposure to show the range of mobility in a part.⁵ This is also used effectively by the Orthopedic Department.

About two years ago it seemed that from the orthopedist's point of view the only external part

employment of operative pictures could be made with profit to both the instructor and the student.

For pathologists, a new method of illumination of gross pathologic specimens was instituted a few years ago.⁷ This method shows the surface texture of fresh specimens, whereas the older methods produced what might be called a "photographic map." Color photography of fresh specimens is often far superior to black-and-white photographs of the same specimen.

Infrared photography can sometimes be used to advantage. It must be remembered that infrared light picks up anything blue, such as veins, and makes it plainly visible if it lies near the skin surface, whereas anything red, such as a skin rash, is completely absorbed and does not register.

It is recommended that all persons in charge of lecture halls, auditoriums, and so forth make a check of projection conditions. To be fair to the lecturers using the facilities of any meeting place, the correct focal-length projection lens for the distance from the projector to the screen should be employed. The largest possible screen should be used, bearing in mind that considerable tabulated

s an erosion. If ulceration occurs, it usually affects only the central portion of the erosion and spares the margin.

Ulceration in cutaneous chancres is, according to Fournier,¹¹ in the vast majority of cases due to necrosis and not to secondary infection. This is the reason why even large ulcerated chancres usually heal with a smooth, superficial scar. The absence of significant bacteriologic findings and the inconspicuous scarring in the case reported here permits the conclusion that the ulceration of the chancres was due to necrosis.

Multiplicity of chancres so far as genital chancres are concerned is not unusual. Most authors have given the incidence as approximately 20 per cent. but some have arrived at considerably higher figures, as, for instance, Driver¹² and Blum,¹³ who encountered multiple genital chancres in 38 and 60 per cent of cases, respectively. In extragenital chancres multiplicity is less frequent and probably does not occur in more than 2 per cent of cases. For example, Bulkley¹⁴ observed 1 case of multiple chancres in 116 cases of extragenital chancres, Krefling,¹⁵ 8 in 280, Montgomery,¹⁶ none in 58, Cole,¹⁷ 1 in 61. Tobias,¹⁸ 3 in 65, Downing,¹⁹ none in 38, and Wile and Holman,²⁰ 1 in 68. In most of the reported cases of multiple extragenital chancres the lesions occurred not on the skin but either in the oral cavity or on modified skin like that of the lips and nipples. Thus, multiple chancres of the extragenital skin can be regarded as uncommon. Still rarer is the presence of chancres at far-distant locations of the skin, as in this case. Queyrat²¹ has applied the name "*chancres multipolaires*" to such cases.

SUMMARY

A case presenting three extragenital cutaneous chancres is reported. The chancres were atypical

in appearance because of their large size and the presence of deep ulceration.

Many extragenital cutaneous chancres have an atypical appearance. Primary syphilis should therefore be considered as diagnosis for all cutaneous ulcers or lesions presenting the diagnostic triad of induration, slow course and satellite adenopathy, particularly if there is a profuse serous secretion and the margin of the ulcer is eroded.

Two days later, scattered brownish-red papules were first noted on the palms and soles.

Ten days after admission, intensive arsenotherapy was begun. For 10 weeks the patient received each week three injections of 0.065 gm. of Mapharsen and one injection of 0.13 gm. of bismuth subsalicylate in oil. The ulcers showed definite evidence of healing 1 week after the first injection of Mapharsen. After 4 weeks of arsenotherapy, two of the lesions — namely, those on the left side of the chin and in

ed as representing a chancre until proved otherwise by repeated darkfield examination of the lesion, as well as of the satellite lymph nodes, and repeated serologic tests.

In addition to lesions that clinically are on slightly suggestive of chancre but harbor *Tre pallidum*, there are lesions that strongly suggest chancre but are nonsyphilitic. Such lesions have been described under the name "pyoderma chancre formis," first by Sánchez Covisa and Bejarano^{3,4} and later by Gougerot,⁵ Hoffmann,⁶ Krantz,⁷ Stryker and others. They occur in the genital region, on the extragenital skin and the oral mucosa. It is thus an exaggeration to state that it is impossible to make a definite diagnosis of primary syphilis from the appearance of a lesion alone. In Stokes's words,⁹ "the diagnosis of the primary lesion is a laboratory, not a physical or morphologic, problem."

Only with this restriction in mind is it advisable to approach a clinical discussion of the chancre. The diagnostic triad mentioned by Stokes for extragenital, cutaneous chancres one might add for ulcerated chancres the following two signs: a profuse purely serous secretion and an eroded border that is usually slightly raised and shows evidence of infiltration. All five signs were present in the lesion

FIGURE 1. Appearance of the Two Chancres Located on the Chin.

the inguinal region — had healed. After 7 weeks, the lesion on the right side of the chin had also healed. Surprisingly little scarring remained, and this was limited to the formerly ulcerated areas. There the skin was smooth, atrophic, depigmented and slightly depressed beneath the level of the surrounding skin. On September 16, 8 weeks after the inauguration of arsenotherapy, Hinton and Wassermann reactions were negative for the first time. They have since remained so. An examination of the spinal fluid on July 27, 1943, was negative.

COMMENT

Chancres frequently do not have the appearance of the typical Hunterian chancre. Milian¹ estimates that only 45 to 50 per cent of all chancres are typical in appearance. He names as atypical forms the giant, dwarf, ulcerated, diphtheroid, crusted and hypertrophic chancre.

Extragenital cutaneous chancres often present an unusual appearance. They are as a rule larger and more inflammatory than the genital variety and are often ulcerated and covered by a heavy crust. The inflammation and induration may suggest a furuncle or carbuncle, the crust of an impetigo (ecthyma) or the ulceration of either carcinoma, tuberculosis or tularemia. Stokes² has therefore stressed the necessity of a "high index of suspicion" when dealing with ulcers or lesions of the skin that present the diagnostic triad of induration, slow course and satellite adenopathy. Lesions presenting these signs should be regarded

FIGURE 2. Appearance of the Chancre Located in the Left Inguinal Region.

of this patient. The presence of an eroded border is believed to be a sign of great diagnostic value. Dreyer¹⁰ has stated that no sign is of such clearness and constancy and so exclusively limited to syphilitic ulcers as is an eroded margin. Its presence is due to the fact that every chancre manifests itself first

Ichs and Peters⁴ emphasize the importance in treatment of meningococcal meningitis of follow-changes in the cerebrospinal fluid by occasional spinal punctures. They treated 39 cases of meningitis and 7 cases of chronic septicemia at Fort Benning, Georgia, with sulfadiazine or sulfadiazine and serotherapy. There were 2 deaths among the patients with meningitis.

Meyer⁵ treated 33 cases of meningococcal meningitis at the station hospital at Camp Grant between January 4 and July 3, 1943, with sulfadiazine, sulfadiazole and polyvalent serum; there were no fatalities. One patient with the clinical picture of the Waterhouse-Friderichsen syndrome recovered.

Smith, Thomas, Dingle and Finland⁶ review 51 cases of meningococcal infection among patients admitted to the Boston City Hospital in the two-year period beginning September 1, 1940. There were 43 patients with meningitis and 8 with septicemia without it. There were 9 deaths among the first group and none in the latter. Group II meningococcus, these authors state, should be carefully distinguished from the gonococcus, especially when the organism is recovered only from the blood. They emphasize the importance of intravenous administration of the initial dose of sulfonamide drug, the judicious use of spinal punctures for the relief of symptoms of increased intracranial pressure and the frequency of pulmonary involvement by the meningococcus.

The use of sulfamerazine in the treatment of meningococcal infections is reported by Lepper, Sweet and Dowling,⁷ by Geffer, Rose, Domm and Flippin⁸ and by Anderson, Oliver and Keefer.⁹ Lepper and his associates gave sulfadiazine to 96 patients and sulfamerazine to 22 patients with meningococcal meningitis. The mortality rate in each group was exactly the same, and the duration of the illness and incidence of complications in relation to the virulence of the infection were also the same. Sulfamerazine seems to be as effective as sulfadiazine. In their hands the former drug was slightly more toxic. Geffer and his associates treated 45 cases of meningococcal meningitis with sulfamerazine. The mortality rate was 7 per cent, which is compared with a 58 per cent mortality in 40 cases of this disease at the Philadelphia General Hospital in 1935-1937, and 40 per cent in 50 cases reported in 1942. The results also compare favorably with the mortality rate of 13 per cent in the patients who were treated with sulfadiazine. Toxic reactions to sulfamerazine were noted in 11 per cent of the treated patients. Anderson, Oliver and Keefer found that sulfamerazine was clinically effective in total doses that were on the average half to one third smaller than the amount of sulfadiazine usually administered. Toxic reactions were in general of the same character and occurred with about the same frequency as did those caused by sulfadiazine.

The prophylactic use of sulfadiazine during an outbreak of meningococcal meningitis is reported by Lewis, Bolker and Klein¹⁰ and by Kuhns, Nelson, Feldman and Kuhn.¹¹ Lewis and his associates cultured the nasopharynx of contacts of patients with meningococcal meningitis. The carrier rate averaged 13 per cent but in some groups was as high as 42 per cent. The carriers were admitted to a special ward and given 2 gm. of sulfadiazine daily for two days and 1 gm. daily for two days. Fluids were forced. No ill effects were noted in 897 carriers. Every person who showed a positive nasopharyngeal culture subsequent to treatment with sulfadiazine was given a course of sulfanilamide. This was necessary in 30 carriers, in all of whom but 1 the culture became negative. The authors state that the use of small doses obviates the risks of toxic reactions to the drug and the need of extensive laboratory facilities. Kuhns and his associates administered 2 gm. of sulfadiazine a day for two days to 15,000 soldiers in residence at two posts where meningococcal meningitis was particularly prevalent during the spring of 1943. Only 2 cases of the disease were reported in the treated cases during a subsequent period of eight weeks' observation, as compared with 40 cases among 18,800 controls. No serious toxic reactions were noted and the treated men continued their usual daily activities.

Fulminating meningococcal septicemia with extensive purpuric hemorrhages into the skin and the adrenal gland has been the subject of numerous reports. Thomas³ found this combination of symptoms, known as the Waterhouse-Friderichsen syndrome, in 17 of 23 patients who died of septicemia and in 1 additional patient there was edema and congestion of the adrenal glands. Blood transfusion, plasma infusion and adrenocortical extract are recommended by Thomas for the treatment of shock in these patients. In a few cases he obtained good results with epinephrine administered by the constant-drip method. Desoxycorticosterone was used but without clear-cut evidence of benefit. Banks and McCartney¹² submit evidence that the meningococcal adrenal syndrome is a composite entity. It can be differentiated into a pure adrenal syndrome and a mixed or encephalitic one. The former is not necessarily fatal. Eleven cases are reported, 8 of which were fatal. Evidently, prompt diagnosis and immediate treatment of the infection with sulfonamide drugs and vigorous replacement therapy for the adrenal crisis may lead to recovery, at least from the pure adrenal syndrome. Gordon and Shimkin¹³ report a case of the Waterhouse-Friderichsen syndrome in which autopsy showed focal necrosis of the pituitary gland, in addition to congestion and microscopic areas of extravasation of red cells into the medulla of the adrenal glands. The authors claim that the changes in the adrenal glands were insufficient to explain the acute adrenal failure, and state that it is possible that the syndrome

MEDICAL PROGRESS

NEUROLOGY*

H. HOUSTON MERRITT, M.D.†

BOSTON

PROGRESS in neurology has been greatly influenced by the war. Publication of results of experimental work in the fundamental sciences has been curtailed because of the shortage of physicians, and because much of the research that is being conducted is along lines of vital importance to the war effort and will not be published until after the war. On the other hand, the increase in the incidence of infectious diseases that always accompanies war has given an opportunity to test newer methods of treatment on large numbers of cases, and the global nature of the conflict has awakened new interest in tropical and other diseases that are seldom seen in this country in normal times. In addition, the injuries to the brain and peripheral nerves occurring in war have stimulated investigative work into the mechanism of cerebral concussion and nerve repair. These two topics are omitted from this article since they will be discussed in the review of advances in neurosurgery.

INFECTIOUS DISEASES

Meningococcal Meningitis

Great strides have been made in recent years in the treatment of meningococcal meningitis. The results obtained with chemotherapy are in striking contrast to those formerly obtained with serotherapy. It is gratifying to note that the use of intraspinal therapy is rapidly being discarded. Uniformly good results in the treatment of meningococcal meningitis by sulfonamide drugs have been reported by various observers. Daniels, Solomon and Jaquette¹ treated 112 patients with meningococcal infections at Fort Bragg, North Carolina, between January 1, 1942, and April 17, 1943. Eighty patients with meningitis and 32 with meningococcemia with no meningitis were treated with sulfadiazine, with only 1 death in the former group and none in the latter. The patients were divided into two groups according to the amount of drug exhibited. The first group received intravenously an initial dose of 0.1 gm. of sodium sulfadiazine per kilogram of body weight, followed by half the initial dose parenterally every eight hours until the patient was able to take the drug by mouth in doses of 1.0 to 2.0 gm. every four hours, so that a blood

concentration of 15 mg. per 100 cc. might be maintained. The second group received intravenously an initial dose of 0.05 gm. per kilogram of body weight, followed in four hours by a dose of 0.05 gm. per kilogram. The dose was repeated every eight hours until the patient was able to take the medicine by mouth. The results in both groups were excellent, but the patients who were treated with the smaller doses required a smaller total dosage of the drug than did the others. The duration of fever and length of stay in the hospital were also less in this group, and renal complications were absent, in contrast to the occurrence of hematuria in 15 per cent and anuria in 7 per cent of the group that received the larger dosage.

Hill and Lever² treated 68 cases of meningococcal infections with sulfadiazine at Camp Edwards, Massachusetts, between January 1 and April 15, 1943, with no fatalities. They stress the importance of early diagnosis and treatment. Treatment can be instituted without waiting for bacteriologic diagnosis when the four combined symptoms, headache, vomiting, chill and rash, are present. These authors emphasize the necessity of administering the initial doses intravenously and the maintenance of an adequate fluid intake. Thirteen of their patients had meningococcemia with no meningitis. Positive blood cultures were obtained in 40 cases. The spinal fluid was clear in 31 of the 62 cases in which a spinal puncture was done. Organisms were frequently recovered from clear fluids.

Thomas³ reports an outbreak of meningococcal meningitis and septicemia in the Fourth Service Command between December, 1942, and June, 1943, during which there were 1935 cases. The mortality rate was 3.3 per cent, which is in striking contrast to the 39 per cent mortality reported by Simmons and Michie for the 6000 cases that occurred in the United States Army during World War I. Two thirds of the cases reported by Thomas developed among new troops, and 80 per cent of the 55 fatal cases occurred in this group. Eighteen of the 46 autopsied cases showed hemorrhages into the adrenal glands. This is regarded as an index to the severity of the septicemia and presents an additional feature for therapeutic consideration. Thomas states that early diagnosis and prompt skillful treatment based primarily on administration of suitable sulfonamide compounds will still be important even if prophylactic chemotherapy prove highly effective.

*From the Department of Neurology, Harvard Medical School, and the Neurological Unit, Boston City Hospital.

chs and Peters⁴ emphasize the importance in treatment of meningococcal meningitis of follow-up changes in the cerebrospinal fluid by occasional spinal punctures. They treated 39 cases of meningitis and 7 cases of chronic septicemia at Fort Benning, Georgia, with sulfadiazine or sulfadiazine and serotherapy. There were 2 deaths among the patients with meningitis.

Meyer⁵ treated 33 cases of meningococcal meningitis at the station hospital at Camp Grant between January 4 and July 3, 1943, with sulfadiazine, sulfadiazole and polyvalent serum; there were no fatalities. One patient with the clinical picture of the Waterhouse-Friderichsen syndrome recovered.

Smith, Thomas, Dingle and Finland⁶ review 51 cases of meningococcal infection among patients admitted to the Boston City Hospital in the two-year period beginning September 1, 1940. There were 43 patients with meningitis and 8 with septicemia without it. There were 9 deaths among the first group and none in the latter. Group II meningococcus, these authors state, should be carefully distinguished from the gonococcus, especially when the organism is recovered only from the blood. They emphasize the importance of intravenous administration of the initial dose of sulfonamide drug, the judicious use of spinal punctures for the relief of symptoms of increased intracranial pressure and the frequency of pulmonary involvement by the meningococcus.

The use of sulfamerazine in the treatment of meningococcal infections is reported by Lepper, Sweet and Dowling,⁷ by Geffer, Rose, Domm and Flippin⁸ and by Anderson, Oliver and Keefer.⁹ Lepper and his associates gave sulfadiazine to 96 patients and sulfamerazine to 22 patients with meningococcal meningitis. The mortality rate in each group was exactly the same, and the duration of the illness and incidence of complications in relation to the virulence of the infection were also the same. Sulfamerazine seems to be as effective as sulfadiazine. In their hands the former drug was slightly more toxic. Geffer and his associates treated 45 cases of meningococcal meningitis with sulfamerazine. The mortality rate was 7 per cent, which is compared with a 58 per cent mortality in 40 cases of this disease at the Philadelphia General Hospital in 1935-1937, and 40 per cent in 50 cases reported in 1942. The results also compare favorably with the mortality rate of 13 per cent in the patients who were treated with sulfadiazine. Toxic reactions to sulfamerazine were noted in 11 per cent of the treated patients. Anderson, Oliver and Keefer found that sulfamerazine was clinically effective in total doses that were on the average half to one third smaller than the amount of sulfadiazine usually administered. Toxic reactions were in general of the same character and occurred with about the same frequency as did those caused by sulfadiazine.

The prophylactic use of sulfadiazine during an outbreak of meningococcal meningitis is reported by Lewis, Bolker and Klein¹⁰ and by Kuhns, Nelson, Feldman and Kuhn.¹¹ Lewis and his associates cultured the nasopharynx of contacts of patients with meningococcal meningitis. The carrier rate averaged 13 per cent but in some groups was as high as 42 per cent. The carriers were admitted to a special ward and given 2 gm. of sulfadiazine daily for two days and 1 gm. daily for two days. Fluids were forced. No ill effects were noted in 897 carriers. Every person who showed a positive nasopharyngeal culture subsequent to treatment with sulfadiazine was given a course of sulfanilamide. This was necessary in 30 carriers, in all of whom but 1 the culture became negative. The authors state that the use of small doses obviates the risks of toxic reactions to the drug and the need of extensive laboratory facilities. Kuhns and his associates administered 2 gm. of sulfadiazine a day for two days to 15,000 soldiers in residence at two posts where meningococcal meningitis was particularly prevalent during the spring of 1943. Only 2 cases of the disease were reported in the treated cases during a subsequent period of eight weeks' observation, as compared with 40 cases among 18,800 controls. No serious toxic reactions were noted and the treated men continued their usual daily activities.

Fulminating meningococcal septicemia with extensive purpuric hemorrhages into the skin and the adrenal gland has been the subject of numerous reports. Thomas³ found this combination of symptoms, known as the Waterhouse-Friderichsen syndrome, in 17 of 23 patients who died of septicemia and in 1 additional patient there was edema and congestion of the adrenal glands. Blood transfusion, plasma infusion and adrenocortical extract are recommended by Thomas for the treatment of shock in these patients. In a few cases he obtained good results with epinephrine administered by the constant-drip method. Desoxycorticosterone was used but without clear-cut evidence of benefit. Banks and McCartney¹² submit evidence that the meningococcal adrenal syndrome is a composite entity. It can be differentiated into a pure adrenal syndrome and a mixed or encephalitic one. The former is not necessarily fatal. Eleven cases are reported, 8 of which were fatal. Evidently, prompt diagnosis and immediate treatment of the infection with sulfonamide drugs and vigorous replacement therapy for the adrenal crisis may lead to recovery, at least from the pure adrenal syndrome. Gordon and Shimkin¹³ report a case of the Waterhouse-Friderichsen syndrome in which autopsy showed focal necrosis of the pituitary gland, in addition to congestion and microscopic areas of extravasation of red cells into the medulla of the adrenal glands. The authors claim that the changes in the adrenal glands were insufficient to explain the acute adrenal failure, and state that it is possible that the syndrome

resulted from damage to the pituitary gland alone or in combination with the minimal adrenal changes and the effects of the septicemia. Herbut and Manges¹⁴ review the history of the Waterhouse-Friderichsen syndrome and report 4 cases. They conclude that there is no proof that death in these cases is due to adrenal failure rather than to toxicity caused by invasion of the blood stream. Williams¹⁵ reports 17 fatalities resulting from acute fulminating meningococcemia. Adrenal hemorrhages were found at autopsy in only 9 of these cases. He concludes that the adrenal hemorrhage is but an incident in an explosive disease process that overwhelms all bodily resistance.

Bernstein¹⁶ reports a case with causalgia of the right arm and purpuric dry gangrene of the toes and scattered areas of the skin as an example of a rare complication of meningococcal meningitis.

Penicillin Therapy in Bacterial Meningitides

There have as yet been few reports in the literature regarding the value of penicillin in the treatment of infections of the nervous system, and its place in the treatment of meningitis, brain abscess and so forth has not been established.

Pilcher and Meacham^{17, 18} report on the use of penicillin in the treatment of meningitis produced experimentally in animals by the intraspinal inoculation of staphylococci and pneumococci. They found that intravenous use of penicillin had no beneficial effect on staphylococcal meningitis. Intrathecal injections, even in small amounts, lowered the mortality rate from 93 to 54 per cent. They resulted in a pleocytosis in the cerebrospinal fluid but no other toxic effects were noted. Similar good results were obtained in the treatment of pneumococcal meningitis. Both intrathecal and intravenous administration of penicillin was necessary in pneumococcal infections, since many of the animals treated only by the intrathecal route died of pneumococcal pneumonia.

Rammelkamp and Keefer¹⁹ studied the concentration of penicillin in the cerebrospinal fluid after intravenous and intrathecal administration in normal subjects and in patients with meningitis. Penicillin did not pass through the blood-brain barrier in significant quantities when injected intravenously. After the intrathecal injection of 5000-10,000 Florey units, penicillin was slowly absorbed and slowly excreted in the urine. It was detected in the cerebrospinal fluid thirty-one hours after injection of 10,000 units. Absorption from the subarachnoid space was more rapid in the patients with meningitis. It was found at autopsy in the fluid from both the cisterna magna and third ventricle of 2 patients who had received the agent intraspinaly several hours before death. In normal subjects the intraspinal injection of 10,000 units caused headache, vomiting, increased intracranial pressure and pleocytosis in the cerebrospinal fluid similar to that seen

after the intraspinal injection of serum, lipiodol or air. The intraspinal injection of 5000 units in normal subjects produced only slight headache and slight pleocytosis in the cerebrospinal fluid. The intrathecal injection of 3000 to 10,000 units in patients with meningitis produced no untoward symptoms. Since penicillin is known to be extremely effective as an antibacterial agent against the streptococcus, pneumococcus and staphylococcus and since meningitis and brain abscess caused by the latter two are resistant to sulfonamide therapy, Rammelkamp and Keefer suggest that the intrathecal injection of penicillin may be a useful method of treating these conditions. Since an effective concentration of the active substance can be maintained for about twenty-four hours without undue toxic reactions, the initial dose should not exceed 10,000 units and subsequent injections of 5000 units may be given every twenty to twenty-four hours. If bacteremia is present, penicillin should be given intravenously as well as intraspinaly.

Evans²⁰ used penicillin in the treatment of 1 patient with pneumococcal meningitis and 2 patients with staphylococcal meningitis, with recovery in all 3 cases. In the first case, pneumococcal meningitis developed following fracture of the skull. In the second case, infection of the meninges by the staphylococcus was secondary to sinusitis and intracerebral abscess. The third patient developed staphylococcal meningitis subsequent to an operation for the removal of a cord tumor in the cervical region. Large doses of penicillin were administered intravenously, intramuscularly and intrathecally in all 3 cases. Sulfadiazine was also used in the treatment of the first patient, but Evans gives the major credit for the cure to penicillin and thinks that its intrathecal administration of penicillin in such cases is of great value.

Cerebral Malaria

Infection with malaria organisms is one of the major problems of military medicine, and as a result the literature of the past year contains numerous articles on various aspects of the infections, including the symptoms and signs of cerebral involvement.

Simpson and Sagebiel²¹ report 12 cases of cerebral malaria that were treated at a United States naval base hospital without a fatality. The dominant symptom was sudden onset of convulsions and coma. An acute confusional psychosis developed in 6 cases. The febrile reactions were highly irregular, with no tendency to follow a forty-eight-hour cycle. The cerebrospinal fluid was examined in 8 cases. It was under increased pressure, and pleocytosis was present in those cases manifesting marked meningeal symptoms. They state that prognosis depends on early diagnosis and prompt treatment. Quinine dihydrochloride, 7½ gr. in 250 cc. of normal saline solution, was administered

ravenously every eight hours until the patients are able to take quinine by mouth. Sedation and absolute bed rest are considered of importance in the therapy.

Galbot²² calls attention to the fact that malaria may stimulate disease of every part of the body, and that the absence of chills and fever should not rule out its occurrence in people who are living in other areas of endemic malaria. He divides the typical cases into twelve groups, four of which are of special interest to the neuropsychiatrist. In one group there are various manifestations of cerebral malaria, with headache, fever and prostration, including medical shock, heat exhaustion, acute delirium, acute mania or an afebrile psychosis. The symptoms clear up or greatly improve on antimalarial therapy. In the second group there is complaint of visual disorder, with headache, often of long duration. Some of the patients have typical optic neuritis, with clouding or dimness of vision, temporal or frontal headache and deep pain in the orbit, which is made worse by ocular pressure. Under antimalarial therapy these patients improve, some with varying degrees of residual visual impairment. Patients in the third group have signs and symptoms of other cranial-nerve involvement, frequently that of the eighth nerve, with resulting vertigo and deafness. A pure malarial basilar meningitis is sometimes seen. The fourth group comprises patients with vague complaints of neuralgia, fatigue or other inconsequential symptoms often labeled as psychoneurotic. The diagnosis of malaria is established by the findings of positive blood smears, and the symptoms are relieved by quinine therapy.

Most and Meleney²³ stress the importance of early diagnosis and adequate treatment of infections with *Plasmodium falciparum*. Unless one is familiar with the extremely varied clinical picture that infection from the organism may assume and the possibility of the development of alarming symptoms requiring early and intensive therapy, the infection may remain unrecognized and may even terminate fatally. Stupor and coma are the most frequent evidences of involvement of the nervous system. In some cases convulsions, stiffness of the neck, hyper-reflexia and the Babinski sign are present. Occasionally there is intermittent rigidity or sucking and grasping reflexes. Incontinence of the sphincters is frequent. On the whole, the clinical picture is similar to that seen in acute meningitis or encephalitis. Mental symptoms are occasionally the outstanding feature at the onset and may result in the admission of the patient to a psychiatric institution. Confusion, restlessness and negativism are usual findings. Such patients must be watched closely, since they may become manic or commit suicide. Quinine dihydrochloride, 6 gm., should be given intravenously every four

hours to patients in coma or with predominant cerebral signs. Spinal drainage may be of value in restoring consciousness. Fluids by vein should be administered freely, and nicotinic acid in doses of 100 mg. should be added to the infusion along with each dose of the quinine dihydrochloride in order to secure maximal dilatation of the cerebral capillaries.

The pathology of cerebral malaria is described by Dhayagude and Purandare.²⁴ In the course of fifteen years they found malarial parasites in the capillaries of the brain in 55 of 97 cases of malaria. Fever and coma were present in 28. Other symptoms included paresis of the limbs, aphasia, dysentery, pneumonia, rigidity of the neck and exaggerated reflexes. The brain appeared grossly normal in 12 of the 55 cases, and in the remaining 43 there was a slate-gray discoloration of the brain substance. On microscopic examination the capillaries of all 55 patients were filled with malarial parasites and their pigment. Punctiform hemorrhages were found in the subcortical region in 2 cases. Malarial granuloma was present in 10 cases. Older granulomas consist of a central capillary surrounded by a mass of neuroglial cells. *P. falciparum* was the infecting type of parasite in the cases with granuloma. The granulomatous lesions, according to these authors, provide the pathological basis for mental disturbances designated as "malarial psychosis."

Subdural Empyema

Kubik and Adams²⁵ present a study of 14 patients with subdural empyema. Their article is the most complete analysis of the clinical features and pathological observations yet recorded in the literature. The sources of infection were paranasal sinusitis in 12 cases, otitis media in 1 case and bronchiectasis with metastatic infection in 1 case. The symptoms in the cases complicating sinusitis were fairly uniform and consisted of exacerbation of chronic sinusitis, orbital swelling, headache, at first localized and later becoming generalized, fever, stiffness of the neck, drowsiness or stupor and focal neurologic signs. Hemiplegia or hemiparesis was present in nearly all cases, and Jacksonian seizures often occurred. The cerebrospinal fluid was under increased pressure, with an increase in cell count and protein content. The sugar content was normal, and the fluids were sterile. The course was rapidly progressive, death in 12 cases occurring within six to twenty days after the onset of the headaches. Two patients recovered after surgical drainage of the empyema. Infection of the subdural space occurred by direct extension through the dura or as a result of thrombophlebitis of the venous sinuses. The subdural pus covered the greater part of the lateral surfaces of the frontal lobe, and in the corresponding area there was a localized subarachnoid exudate but scarcely any generalized leptomeningitis.

gitis. In the underlying cortical gray matter there was severe ischemic necrosis and in most cases thrombosis or thrombophlebitis of the subarachnoid veins. Surgical treatment should consist of drainage through a craniotomy and not through the frontal sinus or a mastoidectomy wound.

Mumps

McGuinness and Gall²⁶ analyze the data on 1378 cases of mumps at Camp McCoy, Wisconsin. Neurologic complications were present in 55 cases (4 per cent). Headache, nausea, drowsiness and stiff neck were the symptoms and signs indicative of involvement of the nervous system in all but 3 of these 55 patients. In these 3 the syndrome was that of a primary subarachnoid hemorrhage in one patient, that of an intracerebral hemorrhage in the second and that of an acute polyneuritis with facial diplegia in the third. The cerebrospinal fluid was bloody in the first two cases, and in the third the fluid contained 16 white cells per cubic millimeter and 135 mg. of protein per 100 cc. The first patient had a mild parotitis, and in the third patient the signs of involvement of the nervous system developed twenty days after the onset of parotitis. In the second case there was no parotitis and the diagnosis of mumps was based on a complement-fixation test. The authors attribute the neurologic involvement in all 3 cases to the mumps infection but it seems more likely that they were only coincidental complications.

Herpes Zoster

Denny-Brown, Adams and Fitzgerald²⁷ report on the pathologic features of 3 cases of herpes zoster. In 2 patients the herpetic eruption was in the thoracic region and the corresponding dorsal root ganglion was the site of an inflammatory necrosis. In addition, there were degeneration of the related motor and sensory roots, severe neuritis, unilateral segmental poliomyelitis and localized leptomeningitis. The third case, with eruption in the occipital and auricular regions and a transient facial (Ramsay-Hunt syndrome) and lingual palsy, was of special interest because of the rarity of autopsy examination in such cases. The authors found necrotizing ganglionitis of the second cervical ganglion, unilateral segmental poliomyelitis in the cervical cord, motor neuritis of the facial nerve and mild inflammatory reaction in the medulla. There was no destruction of the cells in the geniculate ganglion, but some lymphocytic infiltration was present in the fibers of the facial nerve adjacent to the ganglion.

Taterka and O'Sullivan²⁸ report 2 cases of herpes zoster with paralysis and atrophy of muscles of the extremities and summarize the data on 42 previously reported cases. The muscular involvement does not necessarily coincide with the herpetic eruption in localization and extension. The time interval

between the vesicular eruption and appearance of paralysis may range from one day to two months.

Poliomyelitis

The concepts of muscular dysfunction in acute poliomyelitis advanced by Sister Kenny were subjected to analysis by Watkins, Brazier and S.C. and Moldaver.³⁰ Watkins and his associates, who used the electromyograph, state that of the concepts of Kenny the only one upheld by objective measurement is that of inco-ordination and this term is misleading. They demonstrated not only simultaneous activation of protagonist and antagonists but also intermittent synchrony of motor discharges from opposing muscles such as is found in peripheral-nerve injuries during regeneration of axones. "Disordered reciprocal innervation" seems to be a more descriptive term for this type of dysfunction. Moldaver³⁰ explored neuromuscular degeneration in poliomyelitis by the chronaximetry method; the so-called "spasm" was studied in some patients, mostly by electromyograms. He concluded that "spasm" does not lead to neuromuscular degeneration. In paralytic and paretic muscles called "alienated," there is always some degree of neuromuscular degeneration. Among these muscles some are partially denervated; these have a good chance to recover. Others are totally denervated and cannot therefore recover. There is no clinical evidence of so-called "inco-ordination" in the ordinary sense. The patient attempts voluntarily or involuntarily to use a stronger muscle for a weak or paralyzed one. This abnormal use of an extremity is substitution and not inco-ordination.

Rickettsial Diseases

Dyer³¹ reviews the rickettsial diseases and points out the constancy of cerebral symptoms in epidemic and endemic typhus fever. Nervous and mental symptoms are also frequent. In Rocky Mountain spotted fever there are restlessness, insomnia, disorientation and, in severe cases, delirium. In fatal cases coma usually precedes death.

EPILEPSY

Diagnosis

In civil life the diagnosis of epilepsy can be established by observation of the patient over a period of months or years. In military hospitals it is important for various reasons to establish the diagnosis as soon as possible. In patients with infrequent seizures, the main diagnostic aids are electroencephalography and the observation of seizures artificially produced by hydration or overventilation.

Garland, Dick and Whitty³² used the water-Pitressin test in 96 patients, including 20 controls. The patients were kept in bed throughout the test and for twenty-four hours afterward. Five hundred

centimeters of water was given hourly from 8 a.m. until the test was discontinued, the usual amount being 5500 cc. Pitressin was given hourly from 8 a.m. onward, the doses being 0.2, 0.3, 0.4 and 0.5 cc., followed by four doses of 0.5 cc. each. Blood-pressure readings were made at frequent intervals, and the patient was weighed every three days. Fluid intake and output, including vomitus, were also measured to determine the amount of fluid retention. If a fit occurred, the test was stopped at once and 1 gr. of phenobarbital was given by mouth. It was also stopped if there was severe distressing vomiting, abdominal discomfort or severe and persistent headache. Fits usually occurred from 5 p.m. onward. No serious untoward effects were noted. Convulsions resulted in 17 (39 per cent) of the 44 patients with epilepsy, 12 (38 per cent) of the 32 patients with doubtful epilepsy and in none of the 20 control patients with hysterical convulsions.

Swab³³ found the electroencephalogram to be of great value in the diagnosis of epilepsy in a Navy hospital.

Robinson³⁴ tested the value of hyperventilation in the electroencephalogram in the diagnosis of epilepsy. One hundred and forty-six patients were subjected to a six-minute period of hyperventilation. Seizures occurred in 14 (10 per cent). The seizures were of the petit-mal type in 12 patients and of the grand-mal type in 1, and took the form of involuntary crying in 1. The seizures that resulted from hyperventilation were similar to the patient's spontaneous seizures. The petit-mal seizures occurred during hyperventilation. The single grand-mal seizure followed the period of overbreathing by 1 and a half minutes. Of the 14 patients who had a seizure related to hyperventilation, the resting electroencephalogram was abnormal in 12 (85 per cent). The electroencephalogram showed slow waves during hyperventilation in all 14 cases. Robinson concludes that the value of overbreathing in the diagnosis of epilepsy lies in its simplicity of application and the specificity of response that is obtained. It enables the physician to observe the usual seizure pattern. The disadvantages are that seizures result in only a small percentage of cases and that the method requires the active co-operation of the patient. The test does not exclude bizarre hysterical episodes. By contrast the electroencephalogram has the advantages of permanency of record, the need of a minimum degree of co-operation on the part of the subject, the possibility of localizing the focus of a circumscribed lesion and of forms that are often specifically diagnostic in themselves. The disadvantage is the nonspecificity of the abnormal potentials occurring in some of the activities of epileptics, in some persons with mental deficiency, psychosis or behavior disorders and in cases of increased intracranial pressure.

Merritt and Brenner³⁵ report on 3 patients with convulsive seizures who had normal air encephalograms, seven, twenty and thirty months, respectively, after their first convulsions but were subsequently proved to have brain tumors. Cerebral tumors, they say, are not apt to produce any change in the ventricular system unless they are large enough to produce focal neurologic signs or increased intracranial pressure. If in the absence of these it is decided that an air study is advisable, a negative report should not be accepted as conclusive proof that no tumor is present.

Treatment

Cohen, Coombs, Cobb and Talbott³⁶ found that azosulfamide exhibited anticonvulsive action in patients with epilepsy. Associated with the anticonvulsive effects were a decrease in the carbon dioxide power of the serum and an elevation in serum chlorides. In comparing the changes in the serum produced by azosulfamide with those accompanying the administration of phenobarbital they found that a positive potassium balance coincided with the anticonvulsive effect of both drugs. Ammonium chloride produces the same degree of acidosis as does azosulfamide, without alteration of potassium exchange, but the former has no anticonvulsive effect. Phenobarbital produces no acidosis but a positive potassium balance and has an anticonvulsive effect, which suggests that the acidosis is not necessarily the crucial factor in anticonvulsant action.

Davidoff and Doolittle³⁷ used sodium 5-ethyl, 5-(methyl, 1-butenyl) barbiturate (Delvinal Sodium Vinobarbital) in the treatment of patients with convulsive seizures. They found that it was more effective than phenobarbital in the control of petit-mal seizures and did not produce the degree of drowsiness that follows the administration of the latter. Because of its effect on psychomotor activity it is a valuable adjunct to other anticonvulsant drugs, such as Dilantin Sodium, in the treatment of grand-mal or severe motor seizures. Because of its rapid action and relatively low toxicity, the oral administration of the drug is of distinct value in the treatment of serial seizures and their sequelae.

Price, Waelsch and Putnam³⁸ report that *dl*-glutamic acid hydrochloride is beneficial in the treatment of petit-mal and psychomotor seizures. Petit-mal seizures were decreased in frequency, and there was subjective and objective improvement in the mental and physical alertness of the patients. Grand-mal seizures were not affected by administration of the drug.

INTRACRANIAL ANEURYSMS

Intracranial aneurysms continue to receive considerable attention. Sahs and Keil³⁹ review the clinical features in 64 cases in which the diagnosis

of subarachnoid hemorrhage caused by ruptured intracranial aneurysm was made. The presence of aneurysm was verified at autopsy in 12 cases. Eighteen of the 64 patients died in the hospital, 22 were discharged well, and 24 were improved but were left with sequelae such as hemiplegia, ocular palsy, aphasia and disturbance of the visual fields.

From a study of 10 cases, Globus and Globus⁴⁰ conclude that rupture of an intracranial aneurysm into the substance of the brain and into the ventricles is preceded by softening of brain surrounding the vessel. Changes in the brain tissue parallel the progressive pathologic alterations in the aneurysmal wall that culminate in its rupture. The escaping blood breaks through a residual zone of partially softened brain tissue separating the so-called "hemorrhagic cavity" from the adjoining compartment of ventricular cavities, and floods the latter as the fatal termination. A fatal issue occurred as the result of intracerebral and intraventricular hemorrhage in 10 of the 20 verified cases of intracranial aneurysm.

POLYCYTHEMIA VERA

Tinney, Hall and Giffin⁴¹ report neurologic symptoms in 78 per cent of 163 cases of polycythemia vera. Fifty-five patients sought treatment primarily because of neurologic complaints. Subjective complaints, such as weakness, fatigue, insomnia, drowsiness, irritability and loss of memory, were so frequent, nonspecific and varied that patients exhibiting them were thought to have a functional disorder. Objective neurologic signs occurred in 17 per cent of the series and resulted from thrombosis of a cerebral vessel or from cerebral hemorrhage.

PERIODIC PARALYSIS

Brown, Currens and Marchand⁴² describe a hitherto unrecognized syndrome associated with potassium loss in patients with chronic nephritis. The syndrome is characterized by episodes of flaccid paralysis of the extremities resembling that seen in familial periodic paralysis, low T waves in the electrocardiogram similar to those seen in patients with potassium depletion, and signs of chronic nephritis. The authors conclude that the muscular weakness and the electrocardiographic changes are related to the low level of potassium in the serum, which results from the excessive excretion of potassium by the diseased kidneys.

CASE 30321

PRESENTATION OF CASE

First admission. A forty-four-year-old musician entered the hospital because of weakness and tarry stools.

The patient had been in apparent good health until thirteen years before admission, when he developed epigastric pain coming on a few minutes to two hours after meals. It was not severe, was aggravated by excitement and was relieved by soda at first and Amphogel later. It radiated through to the back. The attacks would last for a few weeks and then disappear for months. Eight years before entry he had an episode of feeling faint and noticed profuse perspiration, followed by the passage of a dark molasses-like stool. He fainted and was taken to a hospital in another city. He was given several blood transfusions and was discharged. Since that time he had had recurrent attacks of similar character, for which he was admitted to a community hospital one or ten times. Repeated and extensive studies at that hospital were negative except for blood in the stools and a mild hypochromic anemia, for which he was repeatedly transfused. A gastroscopy was said to show a gastric polyp and possibly a benign peptic ulcer.

Since the first episode the patient had more or less limited himself to a bland diet and had taken six meals daily. Although he led a rather strenuous and perhaps irregular life, he did not drink alcoholic beverages or smoke. Asparagus, turnips and cabbage gave him hives. Fried foods brought about epigastric pain. No statement was made about the relation of the pain and the bleeding. He had had no jaundice or clay-colored stools. He had had no sore tongue, difficulty in swallowing or genitourinary or cardiorespiratory symptoms.

The patient had lived in the Philippines until he was nineteen years old. He had had smallpox as a child but had had no other known illnesses.

Physical examination showed a well-developed, well-nourished pale man in no distress. The heart and lungs were normal. There was moderate mid-epigastric tenderness to deep palpation, but no masses or spasm.

*On leave of absence.

The blood pressure was 120 systolic, 80 diastolic. The pulse was 82, the temperature 99°F., and the respirations 20.

Examination of the blood showed a red-cell count of 5,300,000, with 12 gm. of hemoglobin, and a white-cell count of 7600, with 75 per cent polymorphonuclears, 20 per cent lymphocytes, 2 per cent monocytes and 3 per cent eosinophils. The platelets were normal. A blood Hinton test was negative. The urine was normal. Two guaiac tests on stools were negative. The blood serum nonprotein nitrogen was 24 mg. per 100 cc., and the protein 9 gm. The prothrombin time was normal, and the clotting time 7 minutes. The hematocrit was 46.8 per cent. The corrected sedimentation rate was 1.7 mm. per minute. A second hematocrit was 42 per cent. A bromsulphalein test gave 5 per cent retention. A tuberculin test with a 1:50,000 dilution was negative.

A gastrointestinal series showed a normal esophagus. The stomach contained a small amount of fluid. No definite polyp or ulcer crater could be demonstrated. The duodenal cap was quite tender and on a spot film showed an area suggestive of a small crater on the posterior wall. Fluoroscopic examination of the chest showed areas of increased density in the right upper lobe and shadows that were suggestive of small cavities.

Following the x-ray films of the chest two gastric aspirations were examined for acid-fast bacilli, without success. Sputum examinations were also negative. For a while the patient was put under respiratory precautions. At the end of the second hospital week a gastroscopy revealed a network of what appeared to be dilated veins 1 to 3 mm. in diameter covered with a rather smooth slightly reddened mucosa; they were situated on the anterior wall, extending from the angulus to the cardia. Examination was otherwise negative. A repeat gastrointestinal series showed no additional findings. The patient was discharged against advice on the fifteenth hospital day.

Second admission (five months later). Following discharge the patient was in excellent health for three weeks, having had no recurrence of epigastric pain or of tarry stools. At that time, following an upper respiratory infection, he passed a black stool and was admitted to a community hospital for ten days. There was no further melena and he was sent to this hospital for further studies.

Physical examination was essentially the same as before.

The blood showed a red-cell count of 3,160,000, with 7 gm. of hemoglobin, and a white-cell count of 4200, with 56 per cent polymorphonuclears, 40 per cent lymphocytes and 4 per cent monocytes. The red cells were hypochromic, with moderate variation in the size of the cells. The urine was normal. One stool examination showed a ++ guaiac test. The nonprotein nitrogen was 28.5 mg. per 100 cc., and the protein 8.4 gm., with 6.1 gm. of albumin

and 2.3 gm. of globulin. The cephalin-flocculation test was \pm in twenty-four hours and $++$ in forty-eight hours. A bromsulfalein test showed 5 per cent retention.

A gastrointestinal series revealed considerable thickening of the mucosal folds in the stomach, without definite ulceration. The distal part of the duodenum remained narrow, and there was slight irregularity in the area previously described that was suggestive of a crater. The remainder of the examination was negative. X-ray films of the chest revealed no change from the previous examination. Gastric aspiration showed no acidity in the original contents or in that twenty-four hours after histamine; there was a $+$ guaiac test.

A gastroscopy showed essentially the same findings as noted before, with the addition of two areas on the anterior wall that measured 4 mm. in diameter and were white. There was no blood in the stomach.

The patient was given several transfusions of whole blood, and on the twenty-first hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. E. STANLEY EMERY, JR.* This protocol presents a forty-four-year-old musician who, for thirteen years, had suffered from epigastric distress, which could have been compatible with a duodenal ulcer. For eight years he had been having frequent attacks of gastrointestinal bleeding. Another possibly important point in the history is that he lived in the Philippines until he was nineteen years of age. He is said to have been allergic to certain foods and had what appears to have been a chronic stationary process in the right upper lobe of his lung. X-ray study revealed a narrowing and slight irregularity of the duodenum that was suggestive of a crater, but I gather that it was not considered characteristic for a duodenal ulcer. Furthermore, gastroscopy revealed a curious network of what appear to be dilated veins on the anterior wall of the stomach. The protocol suggests that bleeding was the major problem. From the data presented we have to decide why this patient continued to bleed.

The leading questions are as follows: Did this patient have an ulcer? Was ulcer alone responsible for the bleeding or was there another condition superimposed or co-existent with an ulcer? Was there some condition that was not only responsible for the bleeding but also simulated an ulcer?

Bockus¹ lists twenty-three causes for gastrointestinal bleeding, and it is obvious that in the time allotted I cannot discuss all these causes. I am therefore going to consider the findings as presented with the hope that I may get a clearer idea of the nature of the symptoms and the laboratory find-

ings and then discuss those things that seem pertinent.

The protocol tells us that the patient had been in good health until the age of thirty-one, when he developed epigastric pain that was not severe. I wish that I knew more about the nature of the symptoms because a differential diagnosis involves the question of ulcer may be settled by an accurate evaluation of the symptoms. It might be helpful to know whether the distress coming on a few minutes after eating was the same or different from that beginning two hours after eating. The exact point to which the distress radiated to the back might also have some diagnostic significance.

Eight years before entry he had the first of a number of severe bleeding attacks for which he was studied nine or ten times at a community hospital. All these studies were apparently negative except for a mild hypochromic anemia and a gastroscopy that was said to have shown a gastric polyp. It is a suggestion of a benign peptic ulcer. It would be helpful to know who did the gastroscopy, since the value of procedures of this kind is in direct proportion to the experience and ability of the man performing them. The polypoid appearance may be of significance and will be discussed further later on.

The patient had followed a somewhat limited diet consisting of six meals daily, but we are not told whether the painful symptoms were ameliorated by the frequent feedings. He did not drink alcohol which eliminates one cause of portal cirrhosis. He was allergic to asparagus, turnips and cabbage in that they gave him hives. Fried foods brought on epigastric pain, but we are not told whether this was the same type of pain of which he usually complained. I should like to know this, although I gather little significance was given to this fact since there is no statement that x-ray films of the gall bladder were taken. I cannot lay much importance to this statement because many patients either with or without organic disease, complain of indigestion from fried foods that has to do with the way they are cooked or something of that sort. It is said that no statement was made about the relation of pain and bleeding. I am not sure why this was put in; furthermore, if there were a positive relation, I should not know how to interpret it. The patient had never had clay-colored stools, which is negative evidence for biliary disease. He had had no sore tongue or difficulty in swallowing; in other words, no evidence was found for a deficiency. There were no genitourinary or cardiorespiratory symptoms. The history therefore does not suggest that the bleeding was secondary to cardiac insufficiency.

Having lived in the Philippines until he was nineteen years of age causes us to think of some parasitic infestation as the cause of the gastrointestinal bleeding. I have seen one patient infested with *Ascaris lumbricoides* who had definite attacks of epigastric

*Senior associate in medicine, Peter Bent Brigham Hospital.

simulating an ulcer that were completely re- after expulsion of the worms. Hookworm infection may cause bleeding, usually of a chronic type. Schistosomiasis is another disease that is a frequent cause of bleeding, but the mechanism is a different one, for which there is no evidence in this case. Furthermore, I assume that the patient was thoroughly studied for parasites in the stools and no evidence of their presence is recorded. There was no eosinophilia and, therefore, I think that this possibility can be ignored.

The protein was 9 gm. per 100 cc., and at a later admission, 8.4 gm. with 6.1 gm. of albumin and 2.3 gm. of globulin. This marked elevation of blood protein is difficult to understand, and in talking with Dr. Howard Armstrong he could make only two suggestions: either it was the result of marked dehydration or the test was done in an extremely dry laboratory. The first hematocrit was 46.8 per cent, and the second 42 per cent, neither of which suggests marked dehydration. There is nothing in the patient's history to suggest dehydration, although the cell count was high for a person who had been recently bleeding. The sedimentation rate was very rapid, which may be evidence for something more than a peptic ulcer. A gastrointestinal series showed a dilated duodenal cap and an area suggestive of a crater on the posterior wall. At the time of the first report no mention was made that the duodenum was narrow, but a second report stated that it remained narrow. I wonder if I may see the x-ray films.

DR. LAURENCE L. ROBBINS: These films were looked out at random, and they demonstrate the process in the right upper lobe. The lesion has the appearance of a rather long-standing tuberculous cavity.

DR. EMERY: One wonders whether these findings could have been due to some fungus infection, which, although rare, can produce lesions in the gastrointestinal tract that are responsible for pain and bleeding. Actinomycosis and blastomycosis have both been reported in the duodenum, but they are extremely rare. A second examination of the findings five months later reported no change, which I suppose argues against a fungus or any active process in the chest, but I should like to get the opinion of the roentgenologist on this point.

DR. ROBBINS: It certainly could be a fungus infection.

DR. EMERY: Would the fact that it had not changed in five months tend to rule it out?

DR. ROBBINS: No; furthermore, tuberculosis may show no change by x-ray over a long period of time. The gastrointestinal examinations were done at various times. We can definitely rule out varices of the esophagus. The area that was questioned several times about the possibility of a crater was this narrow distal portion of the cap, but we could never be positive about it. These are thickened

mucosal folds in the cap and make one suspicious of some inflammatory process in that area. The stomach shows some thickening of the mucosal folds and some increase in the amount of secretion, both of which are consistent with gastritis.

DR. EMERY: Are these the dilated veins?

DR. ROBBINS: I doubt if one can recognize a dilated vein 3 mm. in diameter. At the last examination the distal portion of the cap remained narrow.

DR. EMERY: It was not very constricted.

DR. ROBBINS: As you see it is fairly narrow and does not open up to normal width. I see nothing that suggests polyp in the stomach.

DR. EMERY: Am I right in believing that these findings are not characteristic of duodenal ulcer?

DR. ROBBINS: Certainly there is no positive evidence of a crater. It is only suggestive of one.

DR. EMERY: At the end of the second week in the hospital a gastroscopy revealed what, to me at least, is an unusual condition, namely, a network of dilated veins, 1 to 3 mm. in diameter; they were covered with a rather smooth, slightly reddened mucosa and were situated on the anterior wall, extending from the angulus to the cardia. This is an unusual finding and I am not entirely clear from this description just what the condition suggested. If Dr. Edward B. Benedict is here I hope that he will tell us a little more about it. Offhand, it makes one think of an increase in portal pressure, but so far we have nothing else to go with such a condition. It is not my idea of a spider angioma, which, of course, is a cause of frequent and severe bleeding in the gastrointestinal tract. Usually one makes the diagnosis of this condition by finding evidence for it in either the pharynx or larynx, but no mention of any such finding is made.

Schindler² reports having seen dilated veins in only one case and that patient had a carcinoma of the pancreas that was compressing the portal system. He did not state whether esophageal varices were also present. I do not know whether such a condition can be caused by an allergy, although it seems unlikely.

DR. J. H. MEANS: The abstract gives a false impression of Dr. Benedict's findings. I saw this man on the last admission and struggled a great deal, diagnostically speaking. At the first gastroscopic investigation Dr. Benedict found what he believed to be gastric varices but no evidence of esophageal varices. The second gastroscopic examination was different. The findings were consistent with gastric atrophy, and he doubted that the patient had real gastric varices.

The reason the patient spent nineteen years in the Philippines is that he was a Philippino.

DR. EMERY: The patient was discharged against advice but readmitted five months later, having continued to bleed off and on in the interim. The essential findings on the second admission were an

anemia of 3,100,000, a hemoglobin of 7 gm. and a white blood-cell count compatible with this anemia. The serum protein was again elevated, as already mentioned. In addition, a cephalin-flocculation test was \pm in twenty-four hours and $++$ in forty-eight hours, which, to my way of thinking is essentially negative. After several transfusions the patient was explored on the twenty-first hospital day.

In trying to evaluate this case the first question to settle is whether this man had a duodenal ulcer. This we shall have to decide on the basis of the pain radiating through to the back and the intermittency of the distress. It could have been duodenal ulcer, but it was certainly not characteristic of duodenal ulcer. Gastroscoy suggested trouble in the anterior wall of the stomach and, at one time, dilated veins. A later gastroscoy gave the impression of atrophy of the mucous membrane. One thing against ulcer is the somewhat atypical x-ray picture after thirteen years of the trouble. If ulcer was present, could it have explained the peculiar nature of the veins in the stomach? Ulcers, of course, can be responsible for large amounts of bleeding. The general history, the fact that this patient was allowed to go for so long a time without surgery and the fact that the case is being presented for a clinicopathological conference all suggest, however, that something else was responsible for the bleeding.

It is hard for me to believe that this man had a fungus infection for fourteen years. So I shall have to rule it out on that basis. How about tuberculosis? If this was tuberculosis of the lung, and I understand that the x-ray findings were compatible with it, a tuberculous infection could have developed in that portion of the gastrointestinal tract and could have produced chronic lesions that might perhaps bleed from time to time. Against it, however, are the location and the fact that it would be extremely uncommon for tuberculosis to produce as much bleeding as this man had. Although we see tuberculosis around the duodenum at times, the commonest place is in the ileocecal region.

Could the bleeding have been the result of a food allergy? In view of one case that I have observed, it would seem as though it could. This patient was a man of twenty-five who had always suffered from hives on eating certain foods. For some time before we saw him, he had suffered from hunger pains. He entered a hospital because of a recent attack of severe bleeding, which lowered his red-cell count to 2,500,000. Further observations on the part of the physicians and the patient revealed that three conditions were necessary to produce the bleeding: that he eat onions, that he eat a heavy meal with them, and that he be nervously tired. Any one of these conditions alone did not seem to bring on an attack, but the combination of all three inevitably did.

Could allergy explain the gastroscopic appearance in this case? There is little in the literature that I have been able to find along these lines. Schindler²

quotes others but does not give any opinion of his own. Almost all gastroscopic observations on allergic individuals confirm the existence of gastritis. The patient of whom I was just speaking had four gastroscopic studies. Three were in England. The first examiner reported a normal stomach; the second, numerous erosions with bleeding; the third, a large wheal where the speculum touched the mucosa, which bled profusely in fifteen seconds. The fourth examination was made at a large medical clinic, where the mucosa was reported as pale and flaccid, suggesting a chronic type of gastritis. At times, a portion of the membrane became edematous, resembling the mucous membrane of a nasal polyp. One wonders whether the first gastroscopic examination in this patient, which was said to have shown a gastric polyp, may have been a similar type of lesion. It is difficult, however, to explain the dilated veins on the basis of allergy. Could these dilated veins have been the result of increased portal pressure? There is no evidence for liver disease or increased portal pressure other than those veins. S. Burt Wolbach told me that he had seen portal stasis as a result of pressure from enlarged lymph nodes, and another physician told me that he had seen a case in which a duodenal ulcer had caused thrombosis of the portal artery, with retrograde flow. As previously stated, Schindler² reports one case of dilated veins in the stomach, which was the result of a pancreatic carcinoma interfering with the portal circulation.

I do not have the slightest idea what this man had, but in order to make a diagnosis I shall guess that he had a duodenal ulcer, acute allergy and portal involvement causing pressure on the veins. It is possible, in view of the experience with this patient just mentioned, that the bleeding was the result of any one of these things, but was caused by a combination of all.

DR. MEANS: I might tell Dr. Emery that, as far as I know, no one made the correct diagnosis of this man until he was explored — neither the physicians nor the surgeons. When I first saw him, at the time of the last entry, I thought he probably had a splenic-vein occlusion in the splenic vein. I was much impressed with Dr. Benedict's gastroscopic report and appointed when he back-watered on the second day to speak. There are other points that we did not emphasize so much as Dr. Emery has, perhaps we should have. The striking thing was the bleeding. The surgical consultant thought that the man had a duodenal ulcer. I thought that he did not have a duodenal ulcer but I did not know what he had, unless it was splenic-vein occlusion. We could find no evidence of tropical disease. He had been in this country for great many years.

DR. ALLAN M. BUTLER: I have just been looking through the record to check the serum protein values. There is little doubt that they were high. The values varied on repeated analysis from 6.5 to 7.5.

gm. per 100 cc. The albumin-globulin ratios, often the case, were not too constant. Errors were readily made in that determination. In one case the protein was 8.5 gm. and the albumin said to be 6.1 gm. and the globulin 2.4 gm. In another the protein was 8.4 gm., the albumin 5.1 gm., and the globulin 4.5 gm. I should tend to

the surface of the bowel. Here the fat was soft, not boggy, and the lesions were of a constricting nature, with a tendency to encircle the bowel. I was called to the operating room before resection and given the story of bleeding over a long period of time, and I therefore suggested that it might be a Kaposi's sarcoma involving the bowel. There were three or

FIGURE 1.

believe the latter values. It seems to me that with repeatedly high protein levels, one has to consider disease in the liver.

CLINICAL DIAGNOSIS

Duodenal ulcer?
Splenic-vein thrombosis?

DR. EMERY'S DIAGNOSES

Duodenal ulcer.
Acute allergy.
Pressure on portal vein?

ANATOMICAL DIAGNOSIS

Tuberculosis of jejunum, ileum and regional lymph nodes.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: Dr. Leland S. McKittrick operated on this man and was unable to find anything abnormal in the stomach or duodenum. Beginning about 10 cm. from the ligament of Treitz was the first of multiple constricting lesions of the small intestine. The largest lesions were in the proximal 25 cm. of the jejunum and this segment was resected (Fig. 1). The mesentery contained several enlarged nodes, and although the mesenteric fat did not extend very far over the intestine the diagnosis of regional enteritis was considered at operation. In most cases of regional enteritis the fat becomes extremely boggy and extends over

four lesions 2 to 3 mm. in diameter in the ileum, one of which was resected.

When the bowel was opened, the constricting lesions proved to be ulcerations (Fig. 2), and in the gross we thought that the best bet was a regional enteritis. We could not rule out tuberculosis or any other granulomatous process. The microscopic sections showed an acute and chronic process with granulomatous tubercle-like lesions and an occasional giant cell in both the base of the ulcer and the regional nodes. One large node was broken down and suggested caseation. Twenty-five years ago I am sure that most pathologists would have made a definite diagnosis of tuberculosis. Within recent years, however, since Crohn's³ description of regional enteritis and because of the fact that we were unable to find any definite caseation on microscopic examination, we made a tentative diagnosis of regional enteritis. I was examining the slides this morning, not having seen them for a month or so, and the more I looked at them, the more I thought that the process was not characteristic of regional enteritis. I recalled that we had injected some of the material into a guinea pig, and although it was perhaps too early to autopsy the pig, we examined it and found a large node in the groin where the material had been injected. We therefore autopsied the pig and had no difficulty in finding tubercle bacilli in the node. The spleen and the iliac lymph nodes also showed tuberculosis.

Here then is a man who apparently was having chronic bleeding from tuberculosis over a long period of time. I do not recall seeing a similar case. Within recent years we have probably been leaning a little bit too far toward making the diagnosis of regional enteritis when we are confronted with these lesions and rarely consider tuberculosis. It is worth emphasizing the need of guinea-pig inoculation of material from all cases of suspected regional enteritis. The tuberculin test using a dilution of

creasingly weak. Eight months prior to admission he developed extreme urgency and frequency, nocturia ten to twelve times, dribbling and enuresis. The urinary stream was small and intermittent, requiring considerable straining. The urine had a strong odor. He noted a gradually increasing mass in the lower abdomen. Constipation, always a mild one, became severe, requiring Epsom salts or castor oil almost daily, but the stools appeared normal. Six months before entry he developed attacks of pain

FIGURE 2.

1:50,000 was negative; it should have been repeated using stronger dilutions.

DR. EMERY: How about the high serum globulin level?

DR. BUTLER: Dr. William Beckman entered a note in the record suggesting that a granulomatous disease might give a high serum globulin level.

DR. CASTLEMAN: The patient may have had tuberculosis involving the liver at the time of the operation. I do not believe that they examined the liver carefully at that time.

CASE 30322

PRESENTATION OF CASE

A sixty-five-year-old gardener was admitted to the hospital complaining of a mass in the hypogastrium associated with anorexia and increasing weakness.

Fourteen months prior to admission the patient began to complain of anorexia, associated with nausea and vomiting occurring three or four hours after meals. He acquired a distaste for meat, fish and butter and limited his diet to milk, cereal, toast and an occasional egg. His weight, originally 248 pounds, fell to 177 pounds, and he became in-

creasingly weak. Eight months prior to admission he developed extreme urgency and frequency, nocturia ten to twelve times, dribbling and enuresis. The urinary stream was small and intermittent, requiring considerable straining. The urine had a strong odor. He noted a gradually increasing mass in the lower abdomen. Constipation, always a mild one, became severe, requiring Epsom salts or castor oil almost daily, but the stools appeared normal. Six months before entry he developed attacks of pain

mal nocturnal dyspnea relieved by sitting up and medication furnished by his physician. His ankles began to swell, and he developed dyspnea on exertion. At the time he was told that he had hypertension.

The patient claimed to have had rheumatic fever at the age of six, apparently without sequelae. Except for the fact that one sister had tuberculosis the family history was noncontributory.

Physical examination revealed a pale, thin, appearing man. Venous pulsations were visible in the neck. The apical impulse was felt in the anterior axillary line. Rough apical and high-pitched aortic systolic murmurs were audible. There were frequent premature beats. At the base of the right lung in the left axilla, there were flatness to percussion, crackling rales were present. Over the lower thorax of the left chest posteriorly, and to a higher level in the left axilla, there were flatness to percussion, absent tactile fremitus and markedly diminished breath sounds. A nontender, symmetrical, smooth, cystlike mass measuring about 15 cm. in diameter was palpable in the hypogastrium, its upper border reaching a point 5 cm. below the umbilicus. The prostate was markedly enlarged, the right lobe being somewhat larger than the left, and a No. 20 Foley catheter could be passed only with difficulty. There was marked pitting edema of the legs up to the thighs and over the sacrum. The radial vessels were tortuous and very firm. The fundi showed advanced arteriosclerotic changes.

blood pressure was 234 systolic, 84 diastolic. Temperature was 97.6°F., the pulse 70, and the respirations 20.

Red-cell count was 2,180,000, with 6.8 gm. of hemoglobin. The white-cell count was 4600, with 65 per cent neutrophils. A catheterized urine specimen revealed a specific gravity of 1.008 with a negative test for albumin, and contained innumerable red cells, with 8 to 10 white cells and an occasional per high-power field. The serum nonprotein nitrogen was 142.5 mg. per 100 cc. The serum protein was 5.6 gm. per 100 cc., with an albumin-globulin ratio of 2.2. The fasting blood-sugar level was normal. The blood chloride was 109 milliv. per liter, and the carbon dioxide content 14.3 equiv. A blood Hinton test was negative.

Röntgenographic examination of the chest revealed a considerable amount of fluid in the left pleural cavity. The portions of the lungs unobscured by fluid appeared clear. The heart was not remarkable, but the left border was not distinctly demonstrated. A gastrointestinal series revealed some distention of the duodenal cap but no definite ulcer was seen. A barium enema was negative.

The bladder was catheterized, and 500 cc. of urine was withdrawn, following which the abdominal mass disappeared. Constant bladder drainage was instituted. The patient was also given digitalis and placed on a low-salt diet with a daily fluid intake of 2000 cc. orally. On this regime the sacral edema disappeared and the pleural effusion greatly diminished.

On the eleventh hospital day, on getting out of bed, the patient felt faint and everything "went black." He was put back to bed, where he complained of a severe persistent substernal pain. At that time the blood pressure was 160 systolic, 60 diastolic. An electrocardiogram revealed slight ST-segment inversion of T₁ and CF₅, a diphasic T₂, and an upright T₃, CF₂ and CF₄. This was thought to be consistent with either hypertensive or coronary heart disease, or both, but there was no evidence of recent infarction. A portable x-ray film of the chest was unsatisfactory. At that time there was slight tenderness of both calves but no ankle edema.

In the ensuing days, the patient continued to feel weak and faint, complained of persistent epigastric and substernal pain and began to hiccough. The blood nonprotein nitrogen, which had fallen to 87 mg. per 100 cc. on the fourteenth hospital day, began to rise again, gradually reaching 125 mg. The urinary output diminished in spite of a daily fluid intake of more than 2500 cc. The urine had a specific gravity of 1.010, with a + to ++ test for albumin and innumerable white cells. The patient became increasingly lethargic and had constant episodes of retching. On the twenty-second hospital day the temperature rose to 100.2°F. Two days later, the breathing was loud, labored and bubbling, with bronchial breath sounds and numerous coarse rales throughout the chest. A pericardial friction rub and diastolic gallop rhythm

appeared. The patient died on the twenty-fifth hospital day.

DIFFERENTIAL DIAGNOSIS

DR. MARIAN ROPES: In this case, as is true in the cases of many patients of this age, a single diagnosis is not adequate to explain the picture. Several disease processes are apparent with manifestations that were typical, but other changes are hard to explain. I shall start with the more obvious ones.

The patient had hypertension and advanced arteriosclerosis. I assume that the heart disease and the resulting congestive failure were on that basis. In view of the story of rheumatic fever in the past it is impossible to rule out underlying rheumatic heart disease, although there is little evidence for this aside from the fact that an apical murmur of rough quality is more consistent with rheumatic than with arteriosclerotic heart disease; on the other hand, a high-pitched aortic murmur is equally consistent with rheumatic and arteriosclerotic heart disease. I believe, however, that the involvement of the heart was not the primary factor in the picture and was not directly related to the rest of it, except in so far as the severe congestive failure affected the other diseases present, such as renal failure. The pleural effusion on the left I assume to have been secondary to congestive failure. Unilateral effusion resulting from congestive failure occurs on the right side in the majority of cases, but on the left it is not uncommon. The possibility of underlying cancer or tuberculosis has to be considered in view of the rest of the picture.

One other definite fact is a disturbance of the genitourinary tract. The patient had definite prostatic hypertrophy. Not much information is given and it is difficult to determine whether it was benign hypertrophy or cancer of the prostate. I am assuming that it was the former. He surely had urinary infection, which was increased if not originally caused by the obstruction to the outflow of urine from the bladder. The sudden appearance of evidence of obstruction and infection at the same time, however, suggests that infection by the inflammatory reaction it caused at least played a role in the obstruction. Subsequently the patient developed renal failure, in which various factors must have played a role. There was an element of vascular nephritis, although it is difficult to determine the degree. The congestive failure presumably played some role, but without doubt the infection and the obstruction were the most important factors.

Beyond that, the picture becomes less definite. The onset of the illness, with gastrointestinal symptoms, and the subsequent loss of weight and weakness six months before evidence of cardiac failure and of renal disease suggest that these were not directly related to either cardiac failure or renal disease. They do suggest, however, the presence of some underlying disease, which I think was probably cancer, although tuberculosis must surely be kept in mind. The gastrointestinal symptoms

Here then is a man who apparently was having chronic bleeding from tuberculosis over a long period of time. I do not recall seeing a similar case. Within recent years we have probably been leaning a little bit too far toward making the diagnosis of regional enteritis when we are confronted with these lesions and rarely consider tuberculosis. It is worth emphasizing the need of guinea-pig inoculation of material from all cases of suspected regional enteritis. The tuberculin test using a dilution of

creasingly weak. Eight months prior to admission he developed extreme urgency and frequency, nocturia ten to twelve times, dribbling and incontinence. The urinary stream was small and intermittent, requiring considerable straining. The urine had a peculiar odor. He noted a gradually increasing mass in the lower abdomen. Constipation, always a mild irritation, became severe, requiring Epsom salts or castor oil almost daily, but the stools appeared normal. Six months before entry he developed attacks of pain

FIGURE 2.

1:50,000 was negative; it should have been repeated using stronger dilutions.

DR. EMERY: How about the high serum globulin level?

DR. BUTLER: Dr. William Beckman entered a note in the record suggesting that a granulomatous disease might give a high serum globulin level.

DR. CASTLEMAN: The patient may have had tuberculosis involving the liver at the time of the operation. I do not believe that they examined the liver carefully at that time.

THE MEDICAL OFFICER

SURGEON GENERAL KIRK¹ has said, "The human relationship of the doctor, patient and family cannot be laid aside with the donning of the uniform," and Colonel Herrman L. Blumgart,² addressing the members of the graduating class of the Harvard Medical School in December, 1943, emphasized this point when he quoted the legendary exclamation of the soldiers of Charles the Fifth: "We have no longer any fear to die, even if we should be wounded. Paré, our friend, is among us."

Yet such counsel is not always heeded, and there are, unfortunately, a small number of medical officers in the armed forces who have

adopted in their care of the sick and wounded a degree of callousness well calculated to arouse just resentment. Such an attitude on the part of a medical officer, rare though it is, may well cause dislike not only of the physician involved but also of the service of which he is a part. It is possible that such an attitude is fostered by misinterpretation of the rarely heard admonishment, "Remember that you are an officer first, a doctor second." A high-ranking medical officer of the Army, — a man of great experience and with many years of service to his credit, — when asked if a doctor entering the service should adopt such a motto, replied, "If he does, Sir, he may make many enemies."

Every physician in civil life knows that a certain degree of detachment from a patient's plight must be developed if one is to retain one's objectivity. Every officer of the armed forces realizes that there are times — they may be few or they may be many — when his rank must come to the forefront of the situation. Every medical officer knows — as does his civilian counterpart — that there are times when one must crack down on a patient and perhaps be temporarily harsh. But it is well to remember that, as one medical officer of the Navy has said, "a sick or wounded fighting man has something that is just too big for him to handle, and unless he can repose his confidence and faith in you, there is but little to which he can look forward."

To physicians about to enter the armed services — indeed to those who already are medical officers — it might appropriately be said: see to it that neither the strain of battle nor the fatigue of long hours nor the tedium of inactivity nor the restiveness of being in a comparatively minor post nor anything else deter you from the just and proper care of the sick and wounded soldier. Is he — whether wounded, ill or malingering — fundamentally different from his counterpart in civil life? Only in these respects: he is far from home; he is doing something that he does not like; and he may well have been through living hell.

A hospital corpsman who landed with the first Marines on Guadalcanal closed his excellent discussion of this subject with these words: "I have my morphine and I have my tourniquet and my kit, and when I hear the cry 'Corpsman,' I creep up

suggest either direct or indirect involvement of that tract.

This may be a good time to look at the gastrointestinal x-ray films. I judge that they show very little.

DR. MILFORD SCHULZ: They were negative.

DR. ROPES: There was no mass or evidence of extrinsic pressure?

DR. SCHULZ: Nothing.

DR. ROPES: Before attempting to put this together I should like to mention the attack of faintness and precordial pain on the eleventh hospital day. Various possibilities are suggested, such as coronary thrombosis, pulmonary infarct and hemorrhage. The subsequent course and findings, however, do not seem to support any of these. It is possible that the pain was caused by the pericarditis, of which there was evidence later in the form of a friction rub. This I assume was due to uremia. I also assume that the majority of the terminal symptoms were associated with the combination of cardiac failure and renal failure.

In attempting to sum this up, I am sure that this patient had hypertensive and arteriosclerotic heart disease with congestive failure and, terminally, pulmonary edema, presumably not related to the rest of the picture. I also believe that he had benign hypertrophy of the prostate. He certainly had a urinary-tract infection, with obstruction and renal failure, and died in uremia. I also believe that he had some underlying disease, but I find it hard to place, except that it involved the abdomen. It was probably a malignant tumor, the nature of which is not clear. I should guess that it arose primarily in the gastrointestinal tract, although there is little evidence for that. Possibly the genitourinary tract was involved.

DR. WILLIAM C. QUINBY: May I ask why you feel that there must have been some other cause? May not the renal difficulty have accounted for the digestive troubles in the beginning?

DR. ROPES: I thought that the digestive troubles and the loss of weight were out of proportion to the other evidence of renal abnormality.

DR. QUINBY: In my experience it is not uncommon to find an old gentleman coming in complaining of dyspepsia in whom the whole thing is due to an overfull bladder, which he does not realize is present. After the urinary tension is relieved, whether or not he gets well depends on the renal function. I really do not believe that one has to assume that this patient had a malignant tumor in the gastrointestinal tract.

CLINICAL DIAGNOSES

Arteriosclerotic and hypertensive heart disease.

Chronic vascular nephritis.

Uremia.

Prostatic hypertrophy.

DR. ROPES'S DIAGNOSES

Hypertensive and coronary heart disease, with congestive failure.

Pulmonary edema, terminal.

Benign prostatic hypertrophy.

Urinary-tract infection.

Uremia.

Malignant tumor of gastrointestinal tract?

ANATOMICAL DIAGNOSES

Prostatic hyperplasia.

Bronchopneumonia: left lower lobe.

Empyema, left.

Dilatation of bladder.

Hydroureter, bilateral.

Chronic pyelonephritis, slight.

Chronic vascular nephritis.

(Uremia.)

Cardiac hypertrophy.

Coronary sclerosis.

Rheumatic heart disease, with mitral and aortic stenosis.

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN: The autopsy on this man showed an enlarged heart, which weighed over 500 gm. There was no pericarditis. The coronary arteries were severely diseased, but no definite occlusion or infarction could be found. There was moderate rheumatic involvement of both the mitral and aortic valves, with slight calcareous aortic stenosis. In the left pleural cavity there was a liter of turbid, fibrinous fluid surrounding the lower lobe, which was completely solid; on section the consolidation was proved to be due to a confluent bronchopneumonia. I believe that the pneumonia and pleurisy began at the time that the patient had the severe chest pain.

Since there was no pericarditis, the friction rub must have been pleural in origin.

The kidneys together weighed 200 gm. and in gross showed a slight degree of vascular nephritis. Microscopically there were mild vascular changes and some evidence of pyelonephritis. The kidneys on examination would never lead one to believe that this patient had uremia with a nonprotein nitrogen of 140 mg. per 100 cc. He did, however, have some degree of pyelonephritis resulting from the large prostate, which had produced urinary retention. The bladder was markedly distended and trabeculated, and the ureters were slightly dilated.

I believe that a combination of factors produced death. He had a rather severe bronchopneumonia with early empyema, an enlarged decompensating heart and mildly diseased kidneys — all of which combined to put him into a mild state of uremia.

There were also a slightly thickened gall bladder and gallstones, which I do not believe played any role. The gastrointestinal tract was normal, and the enlarged bladder, as Dr. Quinby suggested, probably accounted for the digestive symptoms.

DR. ALLAN M. BUTLER: Would you agree that the prostatic obstruction was the factor in initiating the changes leading to this man's death?

DR. CASTLEMAN: Yes.

food rationing, price administration, sales taxes, travel priorities, labor control and the highest taxes in its history can also do without one other luxury item — an item that millions of its people have never even seen. And while we are not at it, if we have the courage to be about it, let us remove various other loads from the overburdened physician. Let us take away from him the burden of being considered the proper person to decide who is entitled to extra gasoline, for health reasons, or to extra fuel oil on the same basis. Where decisions of this nature are to be made on medical grounds, let medical panels be appointed to make them, without fear or favor. Let us try this time to rescue the doctor from the uncomfortable position that he occupied during the rousing days of prohibition.

MASSACHUSETTS MEDICAL SOCIETY

DEATH

WHITMARSH — Willard F. Whitmarsh, M.D., of Bridgewater, died May 15. He was in his eightieth year. Dr. Whitmarsh received his degree from Harvard Medical School in 1891. He was a member of the American Medical Association.

WAR ACTIVITIES

PROCUREMENT AND ASSIGNMENT

NEEDS OF PUBLIC HEALTH SERVICE

The United States Public Health Service needs 322 physicians immediately. About 170 of these are required for assignment in the War Shipping Administration, for foreign shore duty with the United Nations Relief and Rehabilitation Administration and for sea and foreign shore duty in the United States Coast Guard. The remainder are needed for duties in the Hospital Division, foreign quarantine, tuberculosis control, venereal-disease control and other state control activities.

CORRESPONDENCE

NEW ARMY REGULATIONS FOR MIDDLESEX GRADUATES

To the Editor: I have been informed that interns, resident physicians and practicing physicians who are graduates of the Chicago Medical School or Middlesex University School of Medicine may be considered for commissions in the Army of the United States.

It is my understanding that such practicing physicians who desire consideration for appointment must be licensed to practice medicine and must have completed the regular medical course and have received the M.D. degree from their school, as attested by a letter from their dean; they must have experienced at least one year of rotating internship in a hospital approved for internship; they must hold membership in a local, county or district medical society or, if not meeting residence requirements for membership in any local society, they must submit evidence of actual engagement in the ethical practice of medicine through supporting

letters from three practicing physicians who are graduates of approved medical schools and who are members of the local medical society where the applicant resides. In lieu of such letters, the applicants may submit a letter from the secretary of their local medical society attesting to the applicants' ethical practice of medicine and that they would be eligible to apply for membership in the society had they been in practice for a sufficient length of time.

Graduates of the Chicago Medical School or the Middlesex University School of Medicine in internship or resident training who desire consideration for appointment must be licensed to practice medicine and must have completed the regular medical course and have received the M.D. degree from their school, as attested by a letter from their dean; also they must submit a letter from their hospital vouching for their conduct while in training and indicating that they offer promise of competency in private practice. Such letters must be signed by at least three officers of the staff of the hospital concerned from among the following groups: chairman of the internship committee; superintendent of the hospital; chief-of-staff; and chief-of-staff of one of the special hospital services.

BOOK REVIEWS

To the Editor: I have just read with a great deal of interest the annual report of the librarian of the Boston Medical Library, which appeared in the June 22 issue of the *Journal*. I was particularly impressed with Dr. Viets's comments concerning the Book Review Department of the *Journal*, principally because I thoroughly approve of unsigned reviews, especially when it is obvious that the reviewers are carefully chosen.

We consider the book reviews in the *Journal* to be of unusually high quality, much above that of the average medical book review. Dr. Viets is to be congratulated for the consistently good reviews that appear in the *Journal*. There are far too few constructive criticisms of medical books, and the *Journal*, with its careful reviews, performs a real service not only to its readers but to authors.

BOOK REVIEWS

Physiology of the Nervous System. By John F. Fulton, D.Phil., D.Sc. (Oxon.), S.B., M.D. Second edition, revised and reset. 8°, cloth, 614 pp., with 112 illustrations. London: Oxford University Press, 1943. \$9.00.

In the five years that have passed since the publication of the first edition of this book, there have been many advances in knowledge of the physiology of the nervous system. Professor Fulton has taken cognizance of them and has rewritten his text, bringing it up to date. This monograph deals with the central nervous system, omitting the peripheral and sympathetic systems, except as they are related to the brain and spinal cord. Full accounts of the work of Dussier de Barenne on the sensory cortex and that of Ranson and many others on the deeper structures are given. In fact, no contribution of worth made in the last five years seems to have escaped the author, and this feature, as well as the soundness of his account of former work, makes the book of particular value as a reference volume.

The work on the biochemistry of synaptic transmission of the nerve impulse is fully considered. It is now known that acetylcholine is found in large amounts at the myoneural junction and that it effects the transmission of the nervous impulse across the synapse. This chemical, moreover, is controlled by enzymes — choline esterase, acting to destroy, and choline acetylase, a synthesizing agent. There is therefore a fine balance of a biochemical nature at the junction and, indeed, the same process or a similar process may go on at every point in the nervous system where two neurones are bridged by a synapse. These problems and others now in

on my belly hoping to God that the boy isn't dead before I get there and hoping to God I don't get killed before I reach him, and I give him the morphine and use my tourniquet if it's needed. And I ask you, doctor, What more is there left except encouragement and understanding and tact and the giving out of hope and the gaining of confidence?"

STRADDLING THE ISSUE

ONE interdiction, promulgated by those who watch sleeplessly over the Nation's welfare, that seems to have made little impression on the conscience of the country is the ruling of the War Food Administration relating to the use of heavy cream. Despite the apparent need for the conservation of our milk supply, this regulation, barring from retail sale, except on the prescription of a physician, cream containing more than 19 per cent of butterfat, seems to have acquired in the minds of many the status of an unpopular sumptuary law, possessing neither moral justification nor patriotic appeal.

An investigation has been made into the indispensability of heavy cream in the treatment of the sick, and no competent authority has been cited who is willing to champion any dietary need that cannot be met by the use of 19-per-cent cream with other fats. The Subcommittee on Medical Food Requirements of the Committee on Drugs and Medical Supplies of the National Research Council has denied the indispensability of this form of food; the Council on Foods and Nutrition of the American Medical Association has shown its use to be limited to the production of a ketogenic diet, and has admitted that this diet can be attained satisfactorily by the use of butter, salad oils and cream of the permissible fat content. Chiefs of various hospital services have disclaimed heavy cream as a necessary dietary adjunct; the Boston Medical Milk Commission has declared that its value in medical treatment is unimportant. And yet, according to the *Journal of the American Medical*

Association,* available evidence indicates during the past winter, in New York City, the equivalent of 500,000 quarts of milk went into heavy cream on doctors' prescriptions!

The *Journal of the American Medical Association* suggested a partial remedy for the situation. The War Food Administration has, unfortunately, not accepted the suggestion, which was put into effect as of August 1. The suggestion provides for the endorsement of the physician's prescription for heavy cream by such an official as the health officer or the secretary of the county medical society; the amendment of the War Food Administration reconstructs the suggestion, leaving it the approval of the physician's prescription to the public health officer, or the secretary of the county medical society, of the municipality or county wherein such patient resides." First, the doctor is entrusted with an entirely superfluous responsibility, and then his medical colleague, or perhaps the local druggist, undertaker or carpenter, by virtue of his membership on the local board of health, is set as a watchdog over him!

This new gratuitous irritation seems to be a rather ill-considered way for an earnest, conservative governmental agency to avoid an issue. If there is a real need for the conservation of milk, — and we are constantly told that it exists, — and with heavy cream authoritatively declared to be a negligible factor in the treatment of illness, why, in all conscience, cannot this unnecessary luxury be withdrawn entirely from circulation instead of the doctor being again made the whipping boy, this time for cream to whip!

In Massachusetts, fortunately, this situation has undergone considerable amelioration through the farsightedness and energy of the state director of War Food Administration. This official, unable to obtain rescindment of the amendment, has obtained permission to place his own interpretation on its contents. By this interpretation a committee has been appointed to function in place of the variegated officers originally designated to approve the doctors' prescriptions.

Certainly a democracy at war that can accept selective service, tire confiscation, gasoline, fuel

BOOK REVIEWS

Physiology of the Nervous System. By John F. Fulton, D.Phil., D.Sc. (Oxon.), S.B., M.D. Second edition, revised and reset. 8°, cloth, 614 pp., with 112 illustrations. London: Oxford University Press, 1943. \$9.00.

In the five years that have passed since the publication of the first edition of this book, there have been many advances in knowledge of the physiology of the nervous system. Professor Fulton has taken cognizance of them and has rewritten his text, bringing it up to date. This monograph deals with the central nervous system, omitting the peripheral and sympathetic systems, except as they are related to the brain and spinal cord. Full accounts of the work of Dussier de Barenne on the sensory cortex and that of Ranson and many others on the deeper structures are given. In fact, no contribution of worth made in the last five years seems to have escaped the author, and this feature, as well as the soundness of his account of former work, makes the book of particular value as a reference volume.

The work on the biochemistry of synaptic transmission of the nerve impulse is fully considered. It is now known that acetylcholine is found in large amounts at the myoneural junction and that it effects the transmission of the nervous impulse across the synapse. This chemical, moreover, is controlled by enzymes — choline esterase, acting to destroy, and choline acetylase, a synthesizing agent. There is therefore a fine balance of a biochemical nature at the junction and, indeed, the same process or a similar process may go on at every point in the nervous system where two neurones are bridged by a synapse. These problems and others now in

the forefront of physiologic thought are fully elucidated in this new edition. Professor Fulton has called on many experts, particularly qualified in special fields, to aid him, and their material and the results of his own researches are integrated into each chapter by the author.

The reviewer believed that the first edition of this work was an outstanding contribution to the subject; his opinion is reinforced by the appearance of the second edition, so thoroughly revised and brought up to date. The book can be highly recommended to medical students, physicians and workers in laboratories and libraries. It is, indeed, a fundamental text that should find a place on the shelves of all medical libraries both public and private.

Lectures on Peace and War Orthopedic Surgery. Selected from the instructional courses presented at the eleventh annual assembly of the American Academy of Orthopaedic Surgeons, Chicago, January 17, 18, 19, 20 and 21, 1943. Edited by James E. M. Thomson, M.D. 4°, cloth, 322 pp., illustrated. Ann Arbor, Michigan: Edwards Brothers, Incorporated, 1943. \$4.00.

Usually papers that are read in medical meetings do not have a prolonged appeal or arouse sufficient interest to warrant their separate printing in book form. But here is an exception. This book, a résumé of instructional courses in the orthopedic surgery of war given at the 1943 meeting of the American Academy of Orthopedic surgery, is timely and practical. Dr. James E. M. Thomson has edited the volume in a commendable manner. It is unfortunate that a few of the speakers failed to provide a synopsis of their talks. The book is well illustrated throughout. It is recommended as a valuable addition to the library of those interested in orthopedic surgery.

Gastro-Enterology (in three volumes). By Henry L. Bockus, M.D. Volume 1: *The esophagus and stomach.* 4°, cloth, 831 pp., with 134 illustrations and 21 tables. Philadelphia and London: W. B. Saunders Company, 1943. \$12.00.

This is an excellent book, probably the best on the subject in the last ten years. It is no simple compilation; the opinions are based on the author's large experience. It is well written, interesting and unusually complete, and unlike some books of its size it is not loaded with laboratory methods and types of treatment that are obsolete and have only historical value. It is fully illustrated. The x-ray illustrations are of especially high grade, being clear and definite and having a real purpose, which is a delightful contrast to some of the older textbooks. A great number of well-chosen references are found at the end of each chapter. Habits and fads in diagnosis and treatment are absent; in fact, there is a short section entitled "Avoidance of Enthusiasm for Certain Procedures."

Many controversial subjects, such as the etiology of peptic ulcer, the mechanism of its pain, its transformation into cancer, the value of gastroscopy and its relation to roentgen diagnosis, the relation of gastritis to peptic ulcer and cancer, the best antacids, the treatment of hematemesis by diets, transfusion and operation, and syphilis of the stomach, are treated with good judgment and skill.

The chapters on history taking, histology and physical examination are excellent. Modern methods of examination, such as "spot" roentgen films, gastroscopy, and peritoneoscopy, are freely used and discussed. The author uses the oral tube and fractional gastric analysis by choice, with eight or nine sets of analyses in each case over a two-hour period. Many gastroenterologists still prefer the nasal tube and will not agree that simple examination of fasting contents, with a single test of secretion, "has gradually gone into disuse." The microscopic examination of gastric contents covers ten pages with twenty-three illustrations. This seems rather elaborate in view of its lessened importance in recent years. The Einhorn string test is obsolete and uncertain and could be omitted, also the Woldman phenolphthalein test. The reader is referred to a textbook on laboratory technic for simple tests of the gastric contents. In a book of this size, simple tests for occult blood, lactic acid and so forth could be easily included.

Instead of a fifty-page chapter on roentgenologic examination of the stomach, excellent illustrations and comment are scattered through the book under different diseases. The chapter on gastritis is a great improvement on those

written before the common use of the semiflexible gastroscope. The familiar forty-page chapter on gastric neurosis conspicuous by its absence. There is a good discussion of pain, discomfort, anorexia, bloating and vomiting, nervous or reflex origin under the chapter on syphilis. It is not quite clear why diaphragmatic hernia and hiatal hernia are described separately.

The discussion of peptic ulcer is very complete, taking about 40 per cent of the volume and covering etiology, diagnosis and medical and surgical treatment. Discussion of antacids is particularly useful. Perhaps the variability of magnesium trisilicate preparations should have been mentioned. The chapter on the complications of ulcer and the results that sometimes follow surgery are especially good. The illustrations of many types of gastric tumors are excellent. Syphilis of the stomach is conservatively described.

All in all the book is of high quality and can be heartily recommended.

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Medicine and the War. Edited by William H. Taliaferro, B.S., Ph.D. 8°, cloth, 193 pp., illustrated. Chicago: University of Chicago Press, 1944. \$2.00.

This volume comprises a series of ten lectures by the members of the faculty of the Division of Biological Sciences, University of Chicago. These lectures were sponsored by the Charles Walgreen Foundation and although originally prepared for students, are applicable to the needs of the layman. They deal specifically with food in the war, chemotherapy, malaria, insects, disease, and modern transportation, shock and blood substitutes, aviation medicine, neurologic effects in cerebral injuries, psychiatry in the war, and chemical warfare.

The Health of Children in Occupied Europe. A pamphlet published under the auspices of the International Labour Office. 8°, paper, 37 pp. Montreal: International Labour Office, 1943. 25 cents.

This pamphlet provides a preliminary outline for the study of the effects of war on the health of children. The area covered comprises all the occupied countries of Europe.

NOTICES

HARVARD UNDERGRADUATE ASSEMBLY

The annual undergraduate assembly of the Harvard Medical School will be held in the amphitheater of Building E from 2:30 to 6:00 p.m. on Tuesday, August 29. The program will consist of eight student papers on original clinical and laboratory investigation, followed by an address at 5:00 p.m. by Dr. William T. Salter, professor of pharmacology, Yale University School of Medicine, whose subject will be "Drugs as Biologic Catalysts."

Medical students and physicians are cordially invited to attend.

AMERICAN CONGRESS OF PHYSICAL THERAPY

The twenty-third annual scientific and clinical session of the American Congress of Physical Therapy will be held September 6 to 9, inclusive, at the Hotel Statler, Cleveland. The annual instruction course will be held from 8:00 to 10:30 a.m. and from 1:00 to 2:00 p.m. during the days of September 6, 7 and 8. The scientific and clinical sessions will be given on the remaining portions of these days and evenings. All these sessions will be open to the members of the regular medical profession and their qualified aids.

For information concerning the instruction course and program of the convention proper, address the American Congress of Physical Therapy, 30 North Michigan Avenue, Chicago 2.

DELIRIUM TREMENS*

CARLETON B. CHAPMAN, M.D.†

BOSTON

THE diagnosis and treatment of delirium tremens are usually considered to lie entirely within the province of the psychiatrist; yet the responsibility for the immediate therapy of the condition frequently falls on the general practitioner or internist. To the psychiatrist delirium tremens is an acute toxic psychosis precipitated by prolonged and excessive drinking of alcoholic beverages by persons who perhaps already possess more or less serious psychiatric abnormalities. To the present-day internist it is essentially a problem in sedation, rehydration and vitamin-replacement therapy, whereas to the chronic alcoholic patient it is a terrifying and sometimes fatal hallucinatory illness. Thus, although the nature of delirium tremens and its long-term therapy are essentially psychiatric problems, a practical knowledge of the disorder and its treatment definitely merits the attention of the internist.

DEFINITION AND DIAGNOSIS

In defining delirium tremens, one can hardly do better than consider the layman's expressive term for the disease, namely, "the shakes and the horrors." Practically, the fully developed condition involves several elements, including chronic alcoholism, nervousness, sleeplessness and tremors, and visual hallucinations, occasionally accompanied by other types of hallucinatory experiences. Clinically, one must recognize the incipient as well as the active phase of the disease. In the incipient stage, only tremors and apprehension are noted. With the addition of hallucinations, full-blown delirium tremens is present. Experienced chronic alcoholic addicts are fully cognizant of the incipient phase, "the shakes," and often seek hospitalization soon after its onset in the hope that they can, by means of medical attention, avoid "the horrors." If proper therapy is instituted at this time, the physician is frequently able to spare the alcoholic patient the

truly frightful experience of fully developed delirium tremens. Furthermore, whereas fatalities among the incipient or prodromal group are rare, the same cannot be said for the full-blown condition.

There are several other types of alcoholic psychoses that may easily be confused with delirium tremens. The interesting and excessively rare condition known as alcoholic hallucinosis usually occurs in a younger age group than does delirium tremens, is associated with auditory hallucinations and not generally with visual hallucinations, and is remarkable in that characteristically the patient's insight into his condition is extremely clear. According to Bleuler,¹ such patients are deeply impressed by the content of their auditory hallucinations but paradoxically often recognize them as false sensory perceptions. Only 1 patient with what appeared to be pure alcoholic hallucinosis was admitted to the Second and Fourth Medical Services of the Boston City Hospital during 1941. Delirium tremens may apparently be superimposed on Korsakow's psychosis, but diagnosis of the latter must await clearing of the delirium.

"Rum fits," perhaps better known as "alcoholic epilepsy," are often associated with active delirium tremens but are probably not a manifestation of that condition per se. Finally, various complex and undiagnosable combinations of the alcoholic psychoses are occasionally seen. Such terms as "alcoholic deterioration" or simply "alcoholic psychosis" are not infrequently employed for discharge diagnoses of these cases.

GENERAL INCIDENCE AND MORTALITY

Accurate statistical information on delirium tremens is difficult to obtain. Moore and Gray's² report indicated that 6.2 per cent of the 38,376 patients admitted to the Boston City Hospital for alcoholism in the twenty-year period ending in 1935 had delirium tremens. In the six-year period, from 1936 to 1941, following this report, there were 14,276 admissions for alcoholism to the same hospital, and of these patients 2985, or approximately 21 per cent, were diagnosed as having delirium tremens.

*From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School.

†Formerly, assistant in medicine, Harvard Medical School, and resident physician, Second and Fourth Medical Services (Harvard), Boston City Hospital.

All these figures are, however, based on discharge diagnoses made by a great many different staff members, and include incipient as well as active cases of delirium tremens. The 1941 figures for the Second

Incipient	121	0	0
Active	64	9	14.0 (± 4.4)

and Fourth Medical Services at the Boston City Hospital, based on a personal survey of the case records, appear in Table 1.

A summary of crude death rates for delirium tremens in the literature appears in Table 2. Examination of such data discloses several factors of interest. Moore's⁴ figure is actually an average mortality rate for a twenty-one-year period. The rate for the first year of this period reached the astounding peak of 52 per cent, whereas that for the last

TABLE 2. *Crude Death Rates for Patients with Delirium Tremens, as Reported in the Literature*

AUTHORITY	YEAR	DEATH RATE
Ranson and Scott ³	1911	37.0
Moore and Gray ⁴	1915-1935	24.0
Bowman et al. ⁵

Second period	1939	4.6
Piker and Cohn ⁶	1937	5.3
Rosenbaum et al. ⁷	1940	1.3

year was 14 per cent. Such an average value thus gives little indication of the current mortality. The studies of Rosenbaum et al.⁷ do not include cases having serious complications such as trauma and pneumonia, and their death rate is based on cases of active delirium tremens only. In Table 1, death rates for active delirium tremens and for the total group are given, the latter figure, 4.8 per cent, being roughly comparable with Moore's figure of 14 per cent. No attempt was made to rule out the cases in our series that were complicated by serious illness other than delirium tremens.

AGE, SEX AND RACE INCIDENCE

Active delirium tremens is most frequent between the ages of forty and fifty.⁸ In this series the peak incidence occurred between the ages of thirty and fifty, as shown in Table 3. It may be inferred from the figures in this table that delirium tremens does not develop until constant and heavy alcoholic indulgence has extended over many years. Close consideration, however, indicates that the peak incidence for chronic alcoholism, as reported by Moore,² coincides with that for delirium tremens,

so that conclusions from such figures as to the length of time required for the development of delirium tremens cannot logically be drawn.

Most studies indicate that active delirium tremens occurs far more frequently in men than in women, and the present series, in which only 4 patients, women, is in agreement. This difference is, probably less pronounced than it appears, so

TABLE 3. *Age Incidence in Cases of Active Delirium Tremens Admitted to the Second and Fourth Medical Services of the Boston City Hospital in 1941.*

Total	64	

female alcoholic patients are much more likely to be treated at home than on the wards of a public hospital.

It is striking that of the 62 patients with active delirium tremens none were Jewish, in spite of the fact that about 10 per cent of all patients admitted to the hospital are Jewish. The extremely low incidence of delirium tremens among Jews was commented on by Kat et al.,⁹ who found none in their series of 132 cases seen at the Neuropsychiatric Clinic of the University of Amsterdam, a city having a large Jewish population.

PRECIPITATING FACTORS

Chronic alcoholism, as well as gross malnutrition is intimately associated with delirium tremens. Various concepts and definitions of chronic alcoholism and abnormal drinking have been tabulated by Bowman and Jellinek.¹⁰ It is probably not far from the truth to say that the chronic alcoholic addict is one to whom drinking is life's sole essential activity. In Peabody's¹¹ words, "Normal drinkers are those to whom a night's sleep represents the end of an alcoholic occasion; chronic alcoholics are those to whom a night's sleep is only an unusually long period of abstinence." It is important to note that the emphasis placed on the procuring and partaking of alcoholic beverages by the chronic alcoholic addict often precludes normal activity of any kind. Partial or total abstinence from food concomitant with or as a result of chronic alcoholism is the rule. Practically all observers are agreed that trauma and acute infection frequently precipitate active delirium tremens in chronic alcoholic patients. Some 30 per cent of our cases were complicated by serious infection, including lobar pneumonia and bronchopneumonia, pneumococcal meningitis and in 1 case, miliary tuberculosis. Cases complicated by trauma are admitted to the surgical services and are seldom seen on the medical wards. As a com

ing factor in already serious disease, delirium as must certainly contribute heavily to the lethality in such cases.

Table 4 shows clearly the effect of delirium tremens on pneumonia mortality, as reported by Tilghman in Finland.¹² On statistical examination, the differences in mortality between the group of uncomplicated cases of pneumonia and that of cases

holic patient often undertakes some therapeutic measure at this point. He may, and frequently does, increase his alcoholic intake prodigiously in an effort to "quiet his nerves." Self-medication with paraldehyde is an increasingly frequent occurrence. The fact that the drug is used in hospital practice as an effective sedative in delirium tremens, in addition to the fact that it is procurable in most localities without a physician's prescription, is largely responsible for its increasing popularity among chronic alcoholic patients. Many of our patients with active delirium tremens smell strongly of paraldehyde on admission.

The transition from incipient to active delirium tremens is usually gradual unless precipitated by trauma or severe infection. Mental confusion and disorientation often precede actual hallucinations. Usually, short but vivid visual hallucinations appear first at night. Within the next few hours, the hallucinations may become more frequent and more intense until finally the patient is actively and often dangerously delirious. His response to the hallucinations seems to depend to a large extent on their nature and on his emotional and physical make-up. In general, his actions are obviously motivated by terror, and this fact can hardly be overemphasized. Visual hallucinations are the rule; in addition, auditory hallucinations are frequently but not always present. The objects seen are generally tiny and innumerable, and often direct their threatening activities against the patient himself. The misinterpretation of spots on the bedclothes, leading to plucking movements, is justly considered a classic symptom of active delirium tremens. Snakes, alligators, dogs and other animals frequently figure in the hallucinatory experiences of delirium tremens patients. Some patients complain of countless tiny human forms dancing about the room. A recent patient complained that millions of tiny Japanese soldiers were marching across the floor, up the wall and onto the ceiling in order finally to drop on the bed. Some victims refuse to divulge the nature of their hallucinations, dismissing them as "unmentionable." One female alcoholic patient complained of sleeplessness because she was constantly seeing innumerable cash-register keys and hearing them scream the prices of liquors and cheap wines.

Generally, the hallucinatory phase runs its course in two to four days, although tremors may remain as long as two weeks. If the disease is complicated by serious infection, there may be repeated bouts of hallucinations separated by several days of calm. On recovery from active delirium tremens most alcoholic patients make solemn promises never to indulge again, and at this point they are most susceptible to psychotherapy.

Physical examination in the incipient stage invariably discloses a tremulous, apprehensive person, usually begging for sedation and often smelling of alcohol or, less frequently, of paraldehyde. De-

4. The Effect of Delirium Tremens on Mortality from Pneumococcal Pneumonia.*

DIAGNOSIS	MORTALITY			
	ALL CASES	%	BACTEREMIC CASES	%
Complicated pneumococcal pneumonia	39.8	(±1.6)	79.0	(±2.3)

*Figures are those of Tilghman and Finland¹²; no case received either brom or a sulfonamide.

licated by delirium tremens appear to be fully explained. Although no exact information concerning age distribution of the cases of pneumonia complicated by delirium tremens was available, the difference remained significant when generous allowance was made for this important factor.

CLINICAL FEATURES

In all these cases of delirium tremens, there first occurred a bout of relatively heavy drinking and inadequate food intake, usually lasting from two to six weeks. Rarely the history of such a debauch is withheld by the patient, but in most cases no attempt at concealment was made, although the amounts of liquor consumed were often grossly understated. Early morning drinking is suggestive, since it is well known that persons who drink on rising in the morning frequently do so to calm a shaky hand. The actual amounts of alcoholic beverage consumed vary from a pint to several quarts of various types of liquor. The interrogator should accept with skepticism the statements of a chronic alcoholic addict about his drinking habits, and a negative alcoholic history never rules out delirium tremens as a possibility.

The so-called "prodromal features," such as apprehension, tremors and particularly sleeplessness, are usually considered to indicate incipient delirium tremens. Few cases of active delirium tremens fail to pass through this stage, although the history of it may not be forthcoming. Most patients are chiefly concerned with their inability to sleep, and for this reason many chronic alcoholic addicts become habituated to barbiturates. Apprehension usually develops when the patient realizes that he is about to develop "the horrors," particularly if he has been through the experience before. It is this feature that may send him to a hospital, pleading for admission, in the hope that he will escape the hallucinatory phase of his disease. It is of interest to note that the experienced chronic alco-

hydration, marked by a dry, furrowed tongue and loose, flabby skin, is the rule. The reflexes are often hyperactive. Tremors are best seen in the extruded tongue or in the outstretched hands. Gross generalized somatic tremors may be indicative of a shaking chill, pointing in turn to a complicating infection. Careful examination of the lungs, heart and central nervous system should not be omitted in view of the high frequency of complicating infection or trauma. Generally examination of the abdomen reveals nothing abnormal, but occasionally a rigid and extremely tender abdomen is seen. This condition, known in hospital parlance as the "rum belly," may suggest a perforated viscus with generalized peritonitis, intestinal obstruction or almost any acute abdominal catastrophe. It is variously attributed to acute alcoholic gastritis or to acute pancreatitis, but its true nature is not understood.

Laboratory data indicating dehydration of moderate and occasionally of severe degree are found in the majority of cases. Significant elevations of urinary specific gravity, hemoglobin, white-cell counts and nonprotein nitrogen values are frequently observed. Prompt return of these values to normal occurs in most uncomplicated cases on the administration of fluids.

THE THERAPY

Until comparatively recent times, patients suffering from delirium tremens were usually subjected to no particular treatment other than a jail cell and more or less brutal treatment from unenlightened attendants. The mortality resulting from such treatment will never be known, but it must have been appallingly high. With the introduction of more sympathetic therapeutic measures, the mortality appears to have declined. There remains, unfortunately, much folklore and superstition in connection with the disease in the minds both of the public and of physicians. Some of these concepts are harmless, but some are probably dangerous and should be forthwith abandoned.

Alcohol

A practice still prevalent in Europe is treatment of delirium tremens with alcohol because the condition is allegedly precipitated by abstinence. According to Sheps,¹³ some French clinicians administer alcohol by vein if the patient cannot take it by mouth. One of the most powerful arguments against such therapy is the observation of Piker¹⁴ that from 75 to 90 per cent of patients have delirium tremens while still drinking. Many of the patients with active delirium tremens smell of alcohol on entry, having attempted to ward off this condition by heavier and heavier drinking. Sheps¹³ treated 104 chronic alcoholic patients showing evidence of incipient delirium tremens with hydrotherapy, sedatives and nutritional measures. No alcohol was allowed, yet no case developed active delirium tremens. In

the words of Bowman et al.,⁵ "the administration of alcohol, therefore, either to prevent delirium tremens or as a subsequent therapeutic measure, has no basis in fact, and furthermore often presents an unsurmountable psychologic barrier in the further treatment of such patients."

Spinal Drainage

Therapeutic spinal drainage in delirium tremens was first recommended by Steinebach¹⁵ in Germany and was subsequently advocated by Hoppe¹⁶ in this country, apparently because of a supposed increase in cerebrospinal fluid pressure. More recently Piker and Cohn⁶ attributed their excellent results in delirium tremens therapy in part to spinal drainage. They assumed that there is an irritation to the edema of the brain and meninges and an increase in intracranial pressure. Some doubt was cast on this assumption by Rosenbaum,¹⁷ who after performing lumbar punctures in 234 cases of active delirium tremens concluded that 75 per cent of the patients had normal cerebrospinal-fluid pressure. He made the pertinent observation that it is difficult, under the best of circumstances, to achieve sufficient relaxation for accurate pressure readings in patients suffering from delirium tremens, and suggested that in fact even more than 75 per cent of the patients have normal cerebrospinal fluid pressures. Merritt et al.¹⁸ obtained similar results in examining 201 cases of acute alcoholism, including some cases of delirium tremens.

The finding of the so-called "wet brain" at autopsy in patients dying of delirium tremens is the subject of spirited controversy among neuropathologists, and the relation of such a finding to the disease appears to be in doubt. One is, therefore, forced to conclude that spinal drainage has no rational basis in the therapy of the condition. The measure does not actually alter the clinical course has been established by Rosenbaum, Piker and Lederer.⁷ In carefully controlled clinical experiments, neither spinal drainage nor dehydration measures were found to alter the mortality or clinical course of the disease.

Fluid Therapy

Only comparatively recently has the liberal use of fluids in the treatment of delirium tremens been widely recommended. Piker,¹⁹ who in 1937 recommended spinal drainage and dehydration, re-examined the evidence in 1938. In extensive clinical trials, he was unable to establish the usefulness of fluid limitation and concluded by recommending that fluids be neither limited nor forced. He continued, however, to recommend control of cerebral edema by the judicious use of dehydrants. Bowman, Wortis and Keiser⁵ in 1939 took note of the dehydration exhibited in almost all cases of delirium tremens and recommended full hydration with 3000 to 4000 cc. of fluid per day. They observed

the fluid itself may act as a sedative and that ether medication may be unnecessary. Spinal anesthesia, as well as the use of dehydrating agents, has no place in their therapeutic regime. Wortis,²⁰ in an excellent general review of the subject, states the view that dehydration and spinal drainage are unnecessary and that hydration is a logical and valuable adjunct. Laboratory support for these views is furnished by Cohn,²¹ who found that the blood chloride and carbon dioxide-combining power values were almost always low in delirium tremens, whereas the hemoglobin, serum protein and hematocrit values were increased. He logically concluded that the condition should be treated by restoration of fluid and salt to the body.

It therefore seems unwise and illogical to limit fluids and administer dehydrating agents in a condition of which one of the most constant features is dehydration. In addition, such limitation may inevitably be dangerous, particularly in cases complicated by infection.

Medication

Sedative medication is almost always necessary in treating delirium tremens, and sedation is often difficult to achieve. The older literature contains many recommendations for almost all the known sedatives. The one drug that is almost universally recommended is paraldehyde. Most modern writers^{5, 6} agree that this drug is the most innocuous, the most rapidly eliminated and the most uniformly effective of all sedative medicaments in the treatment of delirium. On the other hand, Henderson and Gillespie²² state that paraldehyde may actually increase the degree of delirium. Sperber²³ holds the same view and states that patients may be fully saturated with the drug and still be actively delirious. Apparent confirmation of this view will have been observed by almost everyone who has had experience in the therapy of delirium tremens. Lano²⁴ offers a plausible explanation for this apparent paradox as follows:

Any chemical sedative, including paraldehyde, if given in fragmentary doses or to individuals who have had other chemical sedatives, may enhance delirium. However, if a patient enters the hospital in incipient delirium tremens and an adequate amount of paraldehyde is given to ensure sleep, it does not provoke the delirium. Certain incipiently delirious patients find themselves on the ascending limb of a delirium and at times paraldehyde is ineffective in checking the course of the delirium.

In other words, adequate doses of paraldehyde will control most cases of active delirium tremens but inadequate doses may well be worse than useless. The initial oral dose recommended by Goodman and Gilman²⁵ is 3 to 8 cc., increased to 10 or 15 cc. if necessary. At the Boston City Hospital, it has been found that single oral doses of less than 8 cc. are of little use in controlling patients with active delirium tremens and that larger initial doses

are indicated. It is highly desirable, as stated by Piker and Cohn,⁶ in all cases of delirium tremens to induce sleep as soon as possible. A rational program to this end is to administer an initial oral dose of up to 16 cc., followed as necessary by oral doses of 8 to 12 cc. every hour. If other measures are adequate, the usual case can be controlled on this regime in two to three hours or less. If the oral route of administration is impossible or impractical paraldehyde can safely be given intramuscularly in doses up to 10 cc. Rectal administration of paraldehyde to actively delirious patients has proved difficult and often impossible in our hands. That the intravenous use of paraldehyde in therapeutic doses may be dangerous is indicated in a recent report.²⁶ Finally, habituation to paraldehyde is not rare, particularly among chronic alcoholic patients who have had repeated bouts of delirium tremens. The drug is actually used as an acceptable substitute for alcohol by some such patients. These facts do not by any means contraindicate the use of paraldehyde in the treatment of active delirium tremens, but when the active phase of the disease is relieved, it is wise to abandon sedatives if possible, or to substitute small doses of barbiturates for paraldehyde if some sedative measure continues to be required.

Barbiturates have been employed much less freely in treatment of delirium tremens than has paraldehyde. One objection is that such large amounts are required that the fatal dose may be approached. Nevertheless, if other measures are adequate, many cases of incipient delirium tremens respond very well to frequent subcutaneous injections of luminal sodium in 3-gr. to 5-gr. doses. The drug is obviously useless in the treatment of active delirium. Sperber,²³ however, used intravenous Evipal Sodium (2 cc. of a 10 per cent solution) to good effect in 3 wildly delirious patients. It should not be forgotten that barbiturates given intravenously may cause serious damage to the liver, particularly in alcoholic patients. Nevertheless, Sperber's suggestion has been followed by us to good advantage in a few particularly violent and obstinate cases. The method is particularly useful in quieting patients who have developed active delirium tremens postoperatively or following severe trauma. In such cases operative wounds may be torn open or further trauma may be inflicted unless the delirium is quickly controlled. The judicious use of barbiturates given intravenously appears fully justified under such circumstances. Morphine has been outlawed in delirium tremens therapy for years, largely because it is said to produce or enhance cerebral edema. Certainly there is nothing to be said in favor of its use in this condition. Apomorphine and strychnine are recommended by Lambert⁸ for severe cases of delirium tremens but are not included in more modern therapeutic

regimens. Scopolamine has been largely abandoned in routine therapy because of the uncertainty of its effect.

Vitamin and Dietary Therapy

Since the introduction of thiamine and nicotinic acid into general use, many reports have appeared purporting to show that they are curative in cases of delirium tremens. Suffice it to say that no report of dramatic success with these agents is convincing. Rapid cures in cases of delirium tremens treated with thiamine have been reported by Kiene et al.,²⁷ Cannon et al.,²⁸ who gave thiamine along with glucose and insulin, and Sciclounoff and Flagg.²⁹ It was Hammargren's³⁰ opinion that thiamine therapy in delirium tremens is sufficiently promising to warrant further investigation. Rosenbaum, Piker and Lederer,⁷ in controlled clinical observations on 36 cases of delirium tremens, found that the patients treated with thiamine required less paraldehyde than did the untreated groups. Nevertheless, they observed that two patients who had incipient delirium tremens on entry developed active delirium tremens after forty-eight hours in spite of large doses of thiamine. Jolliffe et al.^{31, 32} found that nicotinic acid produced dramatic cure in certain cases of alcoholic delirium that they distinguish from delirium tremens as "nicotinic acid deficiency encephalopathy." They point out, however, that in delirium tremens per se they do not consider thiamine or nicotinic acid deficiencies to be etiologically specific, nor do they consider these substances to be curative when used therapeutically. Thus one is forced to agree with Rosenbaum, Piker and Lederer⁷ that, once the disease starts, the addition of thiamine, nicotinic acid, liver extract and brewer's yeast does not aid in shortening the illness.

Nevertheless, to withhold generous quantities of vitamins from patients with delirium tremens appears to be shortsighted and academic. It is a matter of common experience that the patients are badly nourished and subject to gross avitaminoses. For this reason it seems desirable as suggested by Jolliffe et al.,³² to correct faulty vitamin intakes in these patients, although dramatic curative results are not to be expected.

It is extremely important to restore patients who have had delirium tremens to adequate dietary intakes as soon as possible. In unco-operative patients, the administration of large quantities of semi-fluid food rich in carbohydrate and protein by stomach tube is of value. Such mixtures should preferably be divided into small amounts, to be given at frequent intervals.

Miscellaneous Measures

Few writers in recent years have failed to condemn the use of restraint in handling delirious patients, although some authorities recognize it as a necessary evil in situations in which nursing care

is limited. It should be emphasized that the experienced physician is apt to attempt to do with restraint what he has failed to achieve withatives and judicious handling of the patient.

Continuous tub baths for the afebrile or slightly febrile delirium tremens patient are recommended and are used in some clinics with excellent results. This type of therapy is rational and doubtless reduces considerably the amount of sedative medication needed in a given case, but it also requires more facilities and man power than are available in an average public hospital.

Ideally, close attention should be paid to the roundings in which a delirious patient is put. It is often bad practice to leave such patients in darkness, since this seems to increase the terrifying effect of hallucinations. Preferably lighting should be subdued but should extend to every corner of the room. Pictures on the wall are apt to provide the patient with further material for hallucinatory processes. Of extreme importance is the fact that the suicidal or homicidal tendencies of some delirious patients make the leaving of glassware and other loose objects in the room distinctly unwise.

Psychotherapy is of undoubted value in many cases of delirium tremens but is beyond the scope of this paper. In assaying the results of treatment, which is often directed at actual cure of chronic alcoholism, it should not be forgotten that a single bout of full-blown "horrors" is sometimes followed by a prolonged period of abstinence, regardless of the therapy employed. In rare cases, a vigorous bout of delirium tremens may afford sufficient impetus to induce a patient to give up drink altogether.

* * *

In conclusion, although significant advances have been made in the therapy of delirium tremens, the number of deaths still appears to be unnecessarily high, particularly among cases complicated by infection or trauma. Obviously, treatment of complicating illness is of the utmost importance. Nevertheless, prompt control of delirium tremens itself is essential, since proper treatment of the complicating illness is generally impossible until the delirium is controlled or subsides. The mortality among the uncomplicated cases is low and, with regard to this group of patients, one can agree with the conclusion of Rosenbaum et al. that "the problem in delirium tremens at this time is not so much one of discovering the proper method of therapy as it is an elucidation of the etiologic factors involved."

THE WAR AND PUBLIC HEALTH

FREDERICK F. RUSSELL, M.D.*

BOSTON

THE military aspects of public health are many and varied. It is obvious that a healthy army and navy can be recruited only from a healthy population, and one may say without exaggeration that the public health of our nation furnishes the basis on which can be estimated the man power for the armed forces and for the war-production industries. During the present war it has often been wondered why the Italian troops were not better warriors and why their campaigns have not been more successful. Without knowing the reasons for the Italian failures, one may strongly suspect that the principal one has to do with public health in Italy. The Italian public health services have never been particularly distinguished in spite of the fact that a few eminent men have held posts in them. A large part of the population has for endless years been exposed to malaria, a particularly pernicious kind. Experience with this disease has demonstrated that chronic and repeated infections with malaria in endemic areas, such as southern and central Italy, produce a weakened population; not only is the health of the communities at a low level but also the economic condition of the people is depressed. Much of the southern Italian population is involved in a vicious cycle of disease, undernutrition, poor economic status, poor education and, worst of all, a low state of morale and a hopeless outlook for the future. With better public health in Italy the whole course of the Italian war efforts might have been quite different. There is nothing new about this idea, for the decadence of classical Greece has been almost

universally attributed to the invasion of the country by malaria at about the fifth century before Christ. The Greeks in their day could do nothing about this because no one had the necessary knowledge, but this is not true today. Malaria is now well understood, and if the Italians had used the available knowledge of the disease they could in all probability have controlled the greater part of it, just as has been done in this country.

Every activity of a state health department is important to the military services. Even the maternity and infant welfare divisions become fundamentally significant when we find it is obligatory to recruit eight or ten million young men and to enlist under a voluntary system large numbers of young women, and to continue these activities over an indefinite period of years. Everyone hopes that the duration of the war will be short, but the country must nevertheless prepare for a long war or run the risk of losing everything through inadequate preparation. If the states had had better divisions of maternity care and infant welfare during the last twenty years, it might not have been necessary to reject so many young people for disease of one sort or another during the present global war.

In the early days of conscription, before the Nation's actual entry into the war, the number of rejections at recruiting stations was, according to the reports of the selective service boards, about 500 men out of every 1000 examined. The majority of rejections were made because of disease or physical defects, but mental diseases of varying severity accounted for a considerable number. In the early

regimens. Scopolamine has been largely abandoned in routine therapy because of the uncertainty of its effect.

Vitamin and Dietary Therapy

Since the introduction of thiamine and nicotinic acid into general use, many reports have appeared purporting to show that they are curative in cases of delirium tremens. Suffice it to say that no report of dramatic success with these agents is convincing. Rapid cures in cases of delirium tremens treated with thiamine have been reported by Kiene et al.,²⁷ Cannon et al.,²⁸ who gave thiamine along with glucose and insulin, and Sciclounoff and Flagg.²⁹ It was Hammargren's³⁰ opinion that thiamine therapy in delirium tremens is sufficiently promising to warrant further investigation. Rosenbaum, Piker and Lederer,⁷ in controlled clinical observations on 36 cases of delirium tremens, found that the patients treated with thiamine required less paraldehyde than did the untreated groups. Nevertheless, they observed that two patients who had incipient delirium tremens on entry developed active delirium tremens after forty-eight hours in spite of large doses of thiamine. Jolliffe et al.^{31, 32} found that nicotinic acid produced dramatic cure in certain cases of alcoholic delirium that they distinguish from delirium tremens as "nicotinic acid deficiency encephalopathy." They point out, however, that in delirium tremens per se they do not consider thiamine or nicotinic acid deficiencies to be etiologically specific, nor do they consider these substances to be curative when used therapeutically. Thus one is forced to agree with Rosenbaum, Piker and Lederer⁷ that, once the disease starts, the addition of thiamine, nicotinic acid, liver extract and brewer's yeast does not aid in shortening the illness.

Nevertheless, to withhold generous quantities of vitamins from patients with delirium tremens appears to be shortsighted and academic. It is a matter of common experience that the patients are badly nourished and subject to gross avitaminoses. For this reason it seems desirable as suggested by Jolliffe et al.³² to correct faulty vitamin intakes in these patients, although dramatic curative results are not to be expected.

It is extremely important to restore patients who have had delirium tremens to adequate dietary intakes as soon as possible. In unco-operative patients, the administration of large quantities of semi-fluid food rich in carbohydrate and protein by stomach tube is of value. Such mixtures should preferably be divided into small amounts, to be given at frequent intervals.

Miscellaneous Measures

Few writers in recent years have failed to condemn the use of restraint in handling delirious patients, although some authorities recognize it as a necessary evil in situations in which nursing care

is limited. It should be emphasized that the experienced physician is apt to attempt to do a restraint what he has failed to achieve withatives and judicious handling of the patient.

Continuous tub baths for the afebrile or slightly febrile delirium tremens patient are recommended and are used in some clinics with excellent results. This type of therapy is rational and doubtless reduces considerably the amount of sedative medication needed in a given case, but it also requires facilities and man power than are available in an average public hospital.

Ideally, close attention should be paid to the surroundings in which a delirious patient is put. It is often bad practice to leave such patients in darkness, since this seems to increase the terrifying effect of hallucinations. Preferably lighting should be subdued but should extend to every corner of the room. Pictures on the wall are apt to provide the patient with further material for hallucinatory processes. Of extreme importance is the fact that the suicidal or homicidal tendencies of some delirious patients make the leaving of glassware and other loose objects in the room distinctly unwise.

Psychotherapy is of undoubted value in many cases of delirium tremens but is beyond the scope of this paper. In assaying the results of treatment which is often directed at actual cure of chronic alcoholism, it should not be forgotten that a single bout of full-blown "horrors" is sometimes followed by a prolonged period of abstinence, regardless of the therapy employed. In rare cases, a vigorous bout of delirium tremens may afford sufficient impetus to induce a patient to give up drink altogether.

* * *

In conclusion, although significant advances have been made in the therapy of delirium tremens, the number of deaths still appears to be unnecessarily high, particularly among cases complicated by infection or trauma. Obviously, treatment of complicating illness is of the utmost importance. Nevertheless, prompt control of delirium tremens itself is essential, since proper treatment of the complicating illness is generally impossible until the delirium is controlled or subsides. The mortality among the uncomplicated cases is low and, with regard to this group of patients, one can agree with the conclusion of Rosenbaum et al. that "the problem in delirium tremens at this time is not so much one of discovering the proper method of therapy as it is an elucidation of the etiologic factors involved."

THE WAR AND PUBLIC HEALTH

FREDERICK F. RUSSELL, M.D.*

BOSTON

THE military aspects of public health are many and varied. It is obvious that a healthy army and navy can be recruited only from a healthy population, and one may say without exaggeration that the public health of our nation furnishes the basis on which can be estimated the man power for the armed forces and for the war-production industries. During the present war it has often been wondered why the Italian troops were not better warriors and why their campaigns have not been more successful. Without knowing the reasons for the Italian failures, one may strongly suspect that the principal one has to do with public health in Italy. The Italian health services have never been particularly distinguished in spite of the fact that a few eminent men have held posts in them. A large part of the nation has for endless years been exposed to malaria of a particularly pernicious kind. Experience with the disease has demonstrated that chronic and repeated infections with malaria in endemic areas, such as southern and central Italy, produce a weakened population; not only is the health of the communities at a low level but also the economic condition of the people is depressed. Much of the southern Italian population is involved in a vicious circle of disease, undernutrition, poor economic status, poor education and, worst of all, a low state of morale and a hopeless outlook for the future. With better public health in Italy the whole course of the Italian war efforts might have been quite different. There is nothing new about this idea, for the decadence of classical Greece has been almost

universally attributed to the invasion of the country by malaria at about the fifth century before Christ. The Greeks in their day could do nothing about this because no one had the necessary knowledge, but this is not true today. Malaria is now well understood, and if the Italians had used the available knowledge of the disease they could in all probability have controlled the greater part of it, just as has been done in this country.

Every activity of a state health department is important to the military services. Even the maternity and infant welfare divisions become fundamentally significant when we find it is obligatory to recruit eight or ten million young men and to enlist under a voluntary system large numbers of young women, and to continue these activities over an indefinite period of years. Everyone hopes that the duration of the war will be short, but the country must nevertheless prepare for a long war or run the risk of losing everything through inadequate preparation. If the states had had better divisions of maternity care and infant welfare during the last twenty years, it might not have been necessary to reject so many young people for disease of one sort or another during the present global war.

In the early days of conscription, before the Nation's actual entry into the war, the number of rejections at recruiting stations was, according to the reports of the selective service boards, about 500 men out of every 1000 examined. The majority of rejections were made because of disease or physical defects, but mental diseases of varying severity accounted for a considerable number. In the early

*Professor of preventive medicine, emeritus, Harvard Medical School

days of the draft, about 35 men per 1000 were rejected for the latter reason, but later, when the Surgeon General had called special attention to the seriousness of abnormal mental states, the number of rejections increased to about 80 per 1000.

Another cause of rejection at the induction centers that shows an increasing rate is pulmonary tuberculosis. Although the plans of the Army and Navy called for physical examination, including x-ray examination of the chest, of all draftees, it was not possible in the early days of the war to obtain a sufficient number of x-ray machines to do the work. When, however, an adequate number of outfits became available, the rejection rate on account of pulmonary tuberculosis rose from 8 per 1000 in March, 1941, to 16 in January, 1942, and the rate continued to rise to 18 in September, 1942. This does not, of course, mean that the disease is increasing at this rate in the civil population, but merely that improved methods of diagnosis are giving a truer picture of the prevalence of pulmonary tuberculosis than has ever been obtained by the earlier methods. It also demonstrates quite clearly the need for universal x-ray examination of the chest in all properly conducted physical examinations, in civil life as well as in the armed forces.

Rejections because of cardiovascular disease, largely the results of rheumatic fever and of syphilis, amount to about 50 men per 1000. This high rate indicates clearly one of the important fields of study for the future. Cardiovascular disease due to syphilis is surely preventable and as such is of prime importance to all health authorities. In every war an increase in syphilis is to be expected; there will probably be an increase in this one, and the health authorities must make provision for it. Fairly good methods for the control of syphilis are available, and the Scandinavian countries, for example, have been highly successful in applying them. This country has lagged behind and is now faced with a problem of increasing size, so that it is important for health departments to overhaul their venereal-disease programs and make provision for extending and improving them.

Syphilis is a world-wide disease, but its virulence varies considerably in different parts of the world. It is well known that the syphilis of the Caribbean is mild, and it is for this reason that the theory of the American origin of syphilis has always struck me as sound. In the Orient, however, the disease is quite virulent. The syphilis in this country lies between the two extremes: that is, it is moderately severe. So far as is known, both the virulent and the mild forms respond well to the modern treatment that is now available.

Another venereal disease for which we must be on the lookout is lymphogranuloma venereum, which to most practitioners in this latitude is a new disease. It is of common occurrence in the tropics

and particularly so in the Caribbean area. Cases are not infrequent in Puerto Rico, Cuba and Central America. The disease has long been known as climatic bubo, and its venereal origin was for many years unrecognized. Now, however, it is known to be a virus disease acquired by sexual contact and is recognized as a serious public-health problem. It demands correct diagnosis, quarantine of the sort to prevent its spread and the best treatment possible. Unfortunately, up to the present there has been no known specific treatment, and one must do the best one can by expectant treatment. It has recently been determined that the infection, unlike most virus diseases, responds well to the sulfonamide drugs. If further experience shows that these drugs are curative, the task of eradication will be much simpler. Here is a field in which the health authorities should undertake some serious research. Why should they wait for other organizations or universities to solve the problems for them. Research in this field seems not merely a desirable activity but actually a fundamental duty of the health authorities. No one can foretell who will finally solve the problem, but the more investigators interest themselves in this relatively new venereal disease, the sooner will the problem be solved.

Health departments in the past have made notable progress in research, as witness the studies of Chapin, of Rhode Island, on measles; of Park on diphtheria; of the United States Public Health Service on endemic typhus fever, Rocky Mountain spotted fever and the effects of fluorine in the drinking water on mottled tooth enamel; and of the United States Army on yellow fever and typhoid fever. Both the Army and Navy have conducted extensive studies on the physiology of life at the high and low atmospheric pressures occurring in submarines and in the stratosphere. These are only a few examples of research by government bodies.

Cardiovascular disease due to rheumatic fever is still an epidemiologic puzzle, although much more is known about it than was the case during the last war. Many of the studies now being made of hemolytic streptococcus diseases are showing clearly the nature and extent of the problem. Furthermore, the recent experimental use of the sulfonamide drugs in the prophylaxis of streptococcal infections is extremely promising, and it is possible that in the future rheumatic fever and other streptococcal diseases will be much more successfully controlled than in the past. Already it is known that the routine administration of small doses of one or another of these drugs to all recruits during the first weeks of their service in the armed forces cuts down the amount of hemolytic streptococcus disease. As a method of control through the use of drugs, this experiment has been highly successful, but this does not mean that the method will ultimately prove to be either the best or the simplest one. The ad-

stration of any drug to hundreds or thousands of persons at frequent intervals over a period of weeks or months is extremely difficult and expensive, so that the search for some simpler means of control should not be relinquished. Drug control of disease has always been expensive both in money and in personnel. If the environment can be successfully dealt with, this will be easier than dealing with the patient. For this reason, studies are being made in many places to find, if possible, some promising method of control in this puzzling problem.

Micro-organisms in the air of hospital wards and churches, theaters and other places of public assembly can be controlled to a certain extent by the use of ultraviolet light, and also by some of the newer aerosols used as fine sprays.

Vaccination or immunization as a method of control of streptococcal infections has not as yet been successful, perhaps because a mixed group of infections is concerned rather than a single well-standardized disease. Yet one is not justified in giving up the possibility, and research will of course be continued on the subject of immunization as a method of control of the streptococcal infections.

The subject of social medicine after the war deserves consideration. The plans of the Army and Navy for the care of returned soldiers and sailors are elaborate, and since the number of persons to be in care of is extremely large, — already almost 10,000 have been returned to civil life for one reason or another, — it is apparent that this example of social medicine is bound to have a considerable effect on future health policies. Just what will follow is not clear at the time, but it does not seem improbable that a greater interest in all the aspects of social medicine will be aroused. Following the war, the government developed an extensive system of veterans' hospitals, but they have had little direct effect on the practice of medicine. On the other hand, a new and quite successful development in medical care has occurred since the last war; namely, the hospital insurance systems that have sprung up all over the country. The Blue Cross organization for hospital insurance in Massachusetts seems to have been highly successful, and the use of the system on a voluntary basis is increasing. The medical profession and the public have accepted this program quite generally, and it has helped both the patients and the hospitals. The question is now whether the Blue Shield, a sickness insurance on similar lines, will be equally successful.

A good deal has been said about the introduction of exotic diseases by returning soldiers, and the principal disease referred to is malaria. It is unfortunately true that there is much endemic malaria in the several war zones. In North Africa, for example, there is widespread endemic malaria among the native populations, the malarial season is long, and transmission to the American troops is in-

evitable. It will be recalled that in 1880 Laveran discovered the plasmodium of malaria while working with French troops in Algeria. Unfortunately, the disease is still extremely prevalent there, even though sixty years have passed since Laveran made his discovery. From North Africa the troops went to Sicily, and there again were exposed to a population that has suffered from widespread endemic malaria for hundreds of years. When they crossed over the Straits of Messina to invade Calabria and southern Italy the situation was not changed, for malaria is endemic all over southern and middle Italy. It is only during the last ten years that some control has been obtained over the malaria in the Pontine Marshes and the surroundings of Rome.

The endemic malaria of the Mediterranean is not limited to Italy but is equally prevalent east of the Adriatic in Greece, Albania and southern Yugoslavia. Everyone knows of the almost epidemic prevalence of malaria in the islands of the South Seas, particularly in the Solomon Islands. The troops occupying those islands must be replaced at frequent intervals by healthy ones, and the returning troops must be put into rest areas with good hospital facilities, since almost every man in each division will need treatment and care for a time.

Malaria is not an acute disease in the ordinary sense of the word. It is really a relapsing disease that may continue to manifest itself for a year or two after the first attack. It is no longer considered necessary to discharge a man from the service because of malaria, for he can be treated and will recover from the infection just as well while in the service as at home. There are, however, many wounded men and sufferers from some chronic disease, mental or physical, who have malaria in addition to their principal disease, and these men will be sent home for proper treatment and ultimate discharge, when they will play the role of more or less chronic malarial carriers. These are bound to be a considerable element in the population of the Army hospitals at Framingham and Fort Devens. The question to be asked is, How much of a problem do they present to the public health of the adjoining communities? Undoubtedly there will be a considerable number of malaria carriers in the hospitals of this state. Since the disease is never passed along to new victims by contact, but only by the bite of *Anopheles quadrimaculatus*, the anopheline of this region, the number of secondary cases will depend directly on the number of these mosquitoes in the neighborhood of the hospitals. The Army authorities can be counted on to suppress all breeding of anophelines on the military reservations, but this will not be enough to protect the adjoining communities if they have extensive breeding areas. It is therefore obvious that these communities should make a survey of the anopheline population in their townships, so that they may make tentative plans for mosquito control later, provided that it becomes

necessary. Theoretically, it is possible to have extensive malaria in this state, but there is another side to the question. The mosquito breeding season at this latitude is short — probably less than three months each year. The number of anopheline breeding places is probably not very large anywhere in the Commonwealth. Malaria carriers have been coming here from the tropics, from our own South and from Greece and Italy over a period of many years, and the number of secondary cases of malaria that have resulted has been extremely small. There has never been falciparum or tropical malaria or quartan malaria in this region, and the only form that must be planned for is vivax or tertian malaria, which is the mildest of all the forms of the disease, with a low death rate. One must not, however, be too complaisant about the situation, since no one has any idea as to the number of carriers that will be sent here, or just how prolific the anopheline breeding will be in any particular year. All cases of malaria must be reported, and the means of anopheline control must be in readiness in the neighborhood of every Army and Navy hospital.

Some of the malarial relapses will come after the men have been discharged from the armed services and are in their homes. In this situation, the disease must be diagnosed and treated by the local practitioner. He will have the help of the state public-health laboratory and the advice of the district health office, in addition to that of the local health department. This aspect of malaria in Massachusetts should not be a serious one, since the majority of physicians and public-health officers are well trained, the means of communication are unsurpassed, and any local outbreak can be quickly controlled. Such control has not always been easy, however, and in Russia following the last war there was a terrific epidemic of malaria that extended to Archangel, above the Arctic Circle. Much the same kind of catastrophe occurred in the Balkans, and malaria was epidemic there for many years after the war. In both these regions the devastation from the war was colossal and the ways of living were primitive, and it took many years to gain the upper hand over malaria and typhus fever. Conditions in Massachusetts are so different that no such epidemic need be feared. Mosquito and fly screens are in general use, and malaria patients can and should be housed in screened buildings. Adult mosquitoes should be killed by sprays as rapidly as they are discovered. There are enough physicians to make the diagnosis and give the proper treatment, and enough health officers to identify and control the anopheline breeding in every threatened locality.

One fact worth emphasizing is that malaria has never been controlled by the administration of quinine or any other drug to its victims. It has always been necessary to control anopheline breeding to gain the upper hand of malaria transmission,

and in the end this form of control is not only more satisfactory but also much cheaper than the treatment of patients.

Typhus fever is another exotic disease that may cause a great amount of difficulty in North Africa, in Italy and more especially in the Balkans, but it is a louse-borne disease and need not be feared in this state, for since the Civil War we have not been a lousy people. The disease may be introduced by returning troops or by refugees from eastern Europe, but it will not spread. Had the eastern coast of the United States been invaded by the Germans and had the cities been subjected to destruction, the usual protection against lice would have been lacking, but as things are today there is no danger of this. In the area of operations typhus fever among the troops is almost unknown, in spite of the fact that something like 75,000 cases have been reported in the North African native population. Freedom from this infectious disease is owed to two things: an efficient vaccine and a repellent powder that is dusted into the underclothes of each man and promptly kills not only the adult lice but also the nits in the seams of the clothes. The effect of one dose of the powder lasts for several days, and it is easily and inexpensively renewed.

With many prophylactic procedures, such as small-pox vaccination, it is sometimes difficult to secure the co-operation of the public, but in this anti-louse, anti-typhus fever campaign, the natives welcome the new treatment, and in some places they have made themselves more or less of a nuisance by demanding frequent and repeated delousing. One wonders whether the North African, as a result of the prophylactic methods of the health departments of the military and civil governments, may not turn out to be a much more acceptable citizen of the world than he has been in the past. Who knows how far he may advance in his civilization if once he is freed from the diseases that have for so long interfered with his cultural and economic development?

To return for a moment to the personnel of the public-health and medical services: men have been sent from civil life into the armed forces, and, in addition, a large number of recent medical-school graduates have been taken who would ordinarily have gone into practice at home. The total number of doctors involved may be estimated at 50,000. What sort of experience will this large group have in the armed services? To be sure, medicine and public health are the same in principle in peace as in war, but care of the civilian population is different from that of the soldier or sailor. For example, the medical officer does not, as a rule, deal at all with chronic disease or the problems of the aged. The Army or Navy doctor deals chiefly with acute disease, and his prime object is to take care of the lesser diseases and injuries so that his patients may return to the firing line as soon as possible. The

vention and treatment of diseases and of injuries that frequently result in chronic disability, such as tuberculosis, are of course important but for the military man they are less important than the proper treatment of self-limited diseases and for injuries. The physician in civil life spends much more of his time and energy in the care of chronic and more or less disabling diseases, and thus it is seen that there is a wide divergence in the point of view of the military and the civil surgeon.

Medicine in the Army, just as in civil life, includes the specialties, and one of these specialties is preventive medicine. It is safe to say that the percentage of doctors in the armed services who act as health officers is much higher than it is in civil life. Every division and army corps and army has its own health officers and its health-department laboratory and statistical department, and in all commands the senior surgeon is also the health officer. When these men return home to civil life there will be a considerable number who have been active in preventive medicine and health-department activities. Some will then go into health departments, but even if they go into general practice they will understand and be sympathetic with health-department activities.

The health departments have lost many of their members to the Army and Navy, and one wonders whether either they or the public will be satisfied if the old health departments are restored to their former strength and activities. It is impossible to know, but it seems probable that there will have to be better health officials and larger health departments after the war. The medical men and the public have seen or learned of the great advances that have been made during the war in the prevention of disease. They both know that much more can be accomplished in the detection and prevention of tuberculosis, for example, than has been done in the past, and so with many other diseases, such as the venereal diseases. There is no doubt that the public will be willing to pay for the increased activities of the health departments, and thus the physicians of the country will join. Paradoxical as it may seem, it is true that a physician can make a better living in a prosperous, healthy community than he can in a population continually made poor by endemic disease, whatever its nature.

Parasitology promises to be a subject of importance in the post-war world. In this state there are many intestinal parasites — a few round worms, tapeworms and an occasional tapeworm. Returning troops, however, will bring back others. The flies should be examined for parasites, and the sinophilia that goes with many infestations should not be overlooked. The extensive spread of para-

sitic disease need not be feared, since the winters are long and cold and sanitation is good. Nevertheless, the infected patient must have proper treatment.

The importance of psychiatry in post-war medicine and public health is already apparent. The morale of the returned soldier must be kept up, and he must be assisted in finding his niche in a peaceful world. What can be done to prevent the development of neuroses and psychoses is a problem worthy of further study by health departments — national, state and local.

Does the present condition of public health at home and abroad suggest any modification of our own state and local health programs? It is quite true that this state has shown good leadership in the past, and that it has, in general, good laws and flexible regulations, and it is also true that the scientific background on which public-health laws and regulations are based has been conspicuously good.

The administrative side of public health has an interesting history. As times changed and new knowledge became available, the Commonwealth has changed its form of organization, and almost every year has seen some advance in methods of bringing health to the public. Development of state and local health departments is a process that is never finished. What are the present weak points in our organization and what are the changes that should next be made? Health departments based on the small-town system of government are weak and ineffective, and they need constant help from the state health department. One cause of their difficulty is that the board of health is an executive rather than a consultative body and, as is well known, administration by a board rather than by a full-time medical officer of health is necessarily slow and cumbersome. A more modern form of organization is a full-time health officer who has an advisory council, rather than an administrative board of health. The Worcester County board has recently been reorganized on this plan, and the new body may furnish a model for future reorganizations.

Massachusetts has in the past reorganized its public-health system to meet current needs, and it will of course bring its organization into conformity with modern practice. The present is an appropriate time to make plans for the future, since health departments will be more important to the people of all states than they have been in the recent past. Massachusetts has an opportunity again to show its capacity for leadership in public health and its ability to set a model for New England.

ECHINOCOCCAL DISEASE

A Report of Two Cases

THACHER W. WORTHEN, M.D.,* AND JOSEPH F. JENOVESE, M.D.†

HARTFORD, CONNECTICUT

ECHINOCOCCAL disease is most prevalent in the sheep-raising and cattle-raising districts of South America, Australia, South Africa, Central and Northern Europe and the Mediterranean countries of Asia and Africa. In North America 482 cases of hydatid disease in man have been reported since 1808, and of these 22 were indigenous. It is important to bear in mind that a large proportion of the immigrant population of the northern coastal states has come from countries where the disease is most frequently found. It should therefore be considered as a diagnostic possibility when atypical symptoms appear in a patient who has previously lived in one of these countries.

The disease is transmitted from sheep or cattle to dogs, which act as the intermediary host. The human infection results from contact with infected dogs. The ova may be present in the oral secretions or on the fur of the animal. The infection in man manifests itself in the form of cysts, which are either of the unilocular type or contain multiple daughter and even granddaughter cysts.

About 75 per cent of cases of echinococcal disease are found in the liver. Over three quarters of the cysts in the liver are located on the inferior surface of the right lobe so that they extend down into the abdominal cavity. The second most frequent site is the lungs.

In the clinical records of the Hartford Hospital covering a period of seventeen years, 7 cases of hydatid disease were found. Of these, 5 were echinococcal disease of the liver, 1 of the lung and 1 of the gluteal region. Four of the cases showing liver involvement had a cyst on the inferior surface of the right lobe.

This paper is primarily concerned with echinococcal disease of the liver, the symptoms of which may be simply those of a slow-growing tumor, which in time becomes palpable and causes pressure on the biliary tract and in rare cases ruptures.

Echinococcal disease of the liver may be difficult to diagnose because the symptoms may simulate involvement of the biliary tract. The following case report will serve to illustrate this diagnostic problem.

CASE 1. The patient, R. L., was a 41-year-old man who was born in Sicily, where he lived for 27 years. His trade was that of a bricklayer, but he was also employed as a policeman. In the latter capacity he was delegated to watch herds of sheep, and thus the canine contact was established. When he was 27 years old he immigrated to New York City, remaining there only 2 or 3 weeks prior to coming to Hartford, where he had lived since that time.

The patient was first seen by one of us (T. W. W.) in 1932 at which time he gave a history of having had discomfort in the right upper quadrant of the abdomen for approximately 8 years. This discomfort was in the form of typical colicky bladder attacks, pain being referred to the back, associated with vomiting and with dark-colored urine, although jaundice was actually described by the patient. A cholecystogram taken in 1932 revealed a gall bladder with somewhat reduced function but reasonably well outlined. An operation performed purely on the basis of the clinical history revealed slight thickening of the wall of the gall bladder, but no stone. There was an enlarged node along the cystic duct. The liver was perfectly normal in appearance and there was no fibrosis along its edge. No adhesions were present. Cholecystectomy was performed, with an uneventful convalescence.

For some 2 or 3 months after the operation there was relief of the symptoms, but the episodes of distress in the right upper quadrant then began to recur. During the ensuing decade there were from two to five attacks each year.

In March, 1942, the patient was seen by one of us (J. F.). From the past history and symptoms a stone in the common duct was suspected, although there was no jaundice and no bile in the urine. Dietary suggestions were made, and the patient was advised to report when another episode occurred. He was not seen again until 1 year later. At that time he presented the symptoms of an acutely ill patient. The sclerae showed jaundice and the urine contained bile. He stated that he had had a great deal of distress in the right upper quadrant, nausea and vomiting for several days. The stools were clay colored, and there was a positive direct van den Bergh reaction, the bilirubin level being 5.9 mg. per 100 cc. A smooth liver edge was palpable below the costal margin. It was suspected that a stone in the common duct was the basis of the trouble.

An exploratory laparotomy was advised and performed by one of us (T. W. W.). A few intra-abdominal adhesions were encountered. There was an irregular nodular mass just medial to the gall-bladder bed on the inferior surface of the right lobe of the liver. This mass extended from the superior to the inferior border of the liver, and the lower portion of it seemed to involve the hepatic ducts. Its appearance suggested a metastatic lesion, most likely secondary to a primary tumor in the biliary ducts. A biopsy was taken, and in the process a single drop of slightly cloudy fluid escaped.

The patient made an uneventful recovery, and the jaundice and bilirubin cleared up within 1 week. He has returned to work and is in excellent condition, having had no attacks since the operation 8 months ago.

Pathologic examination of the biopsy specimen revealed a chronic granulomatous process with a central mass containing hooklets typical of an echinococcal infection. Subsequent to this report a blood smear was obtained that showed 8 per cent eosinophils.

It is probably true that this patient acquired his infection in Sicily some eighteen years before the diagnosis was made. It would be difficult to believe that there was no visible evidence of echinococcal infection in the liver at the first operation if the operative notes were not so complete.

The only plausible explanations seem to be either that the lesion was beneath the surface of the liver at the time of the first operation or that a small lesion was overlooked, that a very slow growth ensued and that intermittent attacks of mild cholangitis accounted for the symptoms. Finally, a severe acute cholangitis indicated further surgery. In

*Visiting surgeon, Hartford Hospital.

†Assistant physician, Hartford Hospital (on leave of absence)

spect the long duration of the illness was definitely against a stone in the common duct, but nevertheless this was considered the most likely diagnosis. The complete relief of symptoms following the second operation is extremely interesting. This has been purely a coincidence — the cholangitis would have subsided of its own accord. Certainly there was no evidence of a stone in the common duct that manipulation might have dislodged. In any case it is rather too much to expect that this patient will have no further symptoms except for the fact that the natural course of the disease in many cases seems to be a favorable one. It is well to bear this statement in mind as one considers the course of the second case, which presented no obvious diagnostic problem.

CASE 2. M. G., a 34-year-old man born in this country, admitted to the Hartford Hospital in February, 1935, with a mass 6 cm. in diameter in the midepigastrium that had been present for years. Radiologic investigation revealed that the mass was anterior to the stomach. The patient was jaundiced. There was an eosinophilia of 25 per cent. At operation a cyst the size of a large grapefruit was found partially incorporated in the liver substance. The liver itself was riddled with innumerable cysts varying in size from that of the head of a pin to that of a small marble. The contents of the large cyst were completely evacuated, a great many smaller cysts being found, and marsupialization was carried out. The immediate postoperative course was exceedingly uneventful. The patient had a toxic hepatitis and was on the critical list for 8 days. He was finally discharged, however, five weeks after operation with a profusely draining sinus. The

eosinophils had dropped to 2 per cent and have been normal ever since. He returned to work about a year later with a persistent draining sinus that necessitated daily passage of a small catheter to prevent obstruction.

This process continued for the ensuing $7\frac{1}{2}$ years, during which time periodic returns to the hospital were required for the dilatation of the stricture of the sinus, which recurred in spite of the dilatation by catheter.

The sinus has now been closed for 10 months, the liver is not palpable, and the patient is apparently well.

SUMMARY AND CONCLUSIONS

Two cases of echinococcal cyst of the liver have been reported, one of long duration (eighteen years) with symptoms much akin to those of disease of the biliary tract, the diagnosis being made by biopsy at the second operation.

The second case, also of many years' duration, was diagnosed, came to operation, and was finally followed by the spontaneous closure of a sinus resulting from marsupialization. The fact that this patient was a native-born American is unusual but not unknown. It merely serves to emphasize that one cannot make a diagnosis of echinococcal disease purely on the basis of nativity.

The consciousness of the possibility of the occurrence of echinococcal disease of the liver may lead to a diagnosis of this condition in certain cases of atypical biliary-tract disease.

MEDICAL PROGRESS

RECENT ADVANCES IN SURGERY*

ALFRED BLALOCK, M.D.†

BALTIMORE

THE golden age of surgery is said to be that which followed the introduction of methods for producing surgical anesthesia and for lessening the incidence of infections. These and other discoveries widened the scope of surgery to an amazing degree. Undue haste in the performance of operations was no longer necessary. The type of alteration that occurred is illustrated by a quotation from Cushing.¹

The accurate and detailed methods, in the use of which Kocher and Halsted were for so long the notable examples, have spread into all clinics — at least into those clinics where you or I would wish to entrust ourselves for operation. Observers no longer expect to be thrilled in an operating room; the spectacular public performances of the past, no longer condoned, are replaced by the quiet, rather tedious procedures which few beyond the operator, his assistants and the immediate bystander can profitably see. The patient on the table, like the passenger in a car, runs greater risks if he have a loquacious driver, or one who takes close corners, exceeds the speed limit or rides to applause.

*From the Department of Surgery, Johns Hopkins University and Hospital.

†The Shattuck Lecture, delivered at the annual meeting of the Massachusetts Medical Society, Boston, May 23, 1944.

Surgeon-in-chief, Johns Hopkins Hospital, professor of surgery, Johns Hopkins University School of Medicine.

The latter part of the last century is perhaps best known for advances in the surgery of the intestinal tract, of the breast, of hernia, of the thyroid gland and of the pelvic organs. The second and third decades of the present century are perhaps most notable for the advances in neurosurgery, whereas thoracic surgery made great strides in the fourth decade. This division is of course an artificial one, since there has been a steady progress in all phases of surgery. When considered from month to month these advances do not seem very great, but when viewed after a lapse of several years the progress is striking. Many examples could be given that would illustrate the remarkable increase in the number of fields in which surgical therapy is being employed. According to Alexander,² only about 300 cases of pulmonary tuberculosis were reported as having been operated on in the United States between the years 1918 and 1925. It is true that in this particular development we followed at a slow pace the lead of surgeons in other countries. Operations on the heart, the esophagus, the diaphragm,

the lungs, the spinal column, the pancreas, the blood vessels and other structures have increased greatly in number in recent years. It is of interest to consider some of the causes for this increase.

In the first place, a larger number of operations are being performed because of earlier and more accurate diagnosis. This fact is due not so much to improvements in methods of history taking and physical examination, which have advanced very little in recent years, as to advances in other diagnostic methods. Notable among these is the more frequent use of the roentgen ray, together with the employment of various contrast mediums. It would be impossible today to practice surgery effectively without the benefit of the knowledge gained from the gastrointestinal series, the barium enema, cholecystography, pyelography, ventriculography, bronchography and arteriography. What satisfaction must attend Dr. Cannon, Dr. Graham, Dr. Dandy and others who have been responsible for advances that have resulted in the earlier and the more accurate diagnosis of various diseases! A number of years ago most operations were listed as exploratory procedures. This meant that one was usually in doubt where to make the incision, was frequently unable to locate the diseased area at the time of operation if changes were minimal and usually had to cause a good deal of trauma to normal parts in order to locate the site of the disease. A striking example of the value of the roentgen ray is shown in the recognition of diaphragmatic hernias. In 1938 Harrington³ stated that the condition was recognized at the Mayo Clinic in more than twenty-three times as many cases in the last twelve years as in the previous eighteen years.

Surgery must prove itself continually in that the benefits to be derived from an operation must outweigh the risk to life, the discomforts, the loss of time and the expense. Earlier diagnosis has been an important element in reducing the morbidity and mortality rates associated with operations. This in turn has given patients an increased confidence in what can be accomplished by surgical means, and there is less tendency on the part of the public to conceal trouble until far-advanced disease is present. The intelligent use of the roentgen ray has played a major part in this transformation. It appears to be a safe prediction that, in the future, roentgenographic studies of the chest will be made routinely on all patients. Already many asymptomatic disorders of the chest have been discovered during examination of recruits for military duty. It is just as important that the surgeon should have the advantage of the opinion of a good roentgenologist as that he should have the advice and counsel of a good internist.

Advances in the knowledge of the causes of disease also have widened the scope of surgery. Operations on the parathyroid and adrenal glands and the pancreas have ceased to be of rare occurrence.

A better understanding of the functions of the sympathetic nervous system and its relation to various diseases has multiplied many times the number of operations on this system. Similar statements might be made about various other parts of the body.

Advances in the preoperative and postoperative care of patients have played a large part in the progress of surgery. Rarely today are emergency operations performed on moribund patients, since most cases means are available for improving the condition. Hemorrhage that is uncontrollable by nonoperative means is one of the few indications for immediate operation. One is seldom justified in operating before dehydration or acidosis and other such conditions have been corrected. Fortunately, the patient consults the physician earlier today than previously, and the difficulties connected with the preparation of the patient are relatively fewer. The incidence of preoperative complications has diminished considerably, and means are available for dealing effectively with a good many of those that do occur.

Measures that are helpful in preventing pulmonary embolism deserve special emphasis. These include an appreciation of the value of frequent alteration of the position of the patient, of the use of heparin and dicumarol and of ligation of the femoral vein when indicated. Notable among the recent achievements are the various chemotherapeutic agents for preventing and combating infection and the several different methods by which intestinal distention due to a number of causes can be relieved. Great credit is due Drs. Collier and Maddock for their important studies on fluid balance in surgical patients. The problem of the feeding of patients by the intravenous route is only partly solved, but even so the results are significant and encouraging. Some of these advances will be commented on later. Lord Moynihan has said that surgery has been made safe for the patient and that we must now make the patient safe for surgery. Important strides have been made in this direction but it is likely that the next several decades will see greater progress.

It is difficult to assess the advances in anesthesia from year to year, but the progress from decade to decade is fully evident. There are improvements in methods of administration as well as a larger number of satisfactory agents from which one may choose. There are now many anesthetists and surgeons who can choose in an intelligent manner the best anesthetic agent for the patient in question. The reduction of untoward incidents both during and following operation is due in no small measure to such advances.

There is probably no measure that has contributed more to the manner in which operative procedures of great magnitude are withstood by patients than the copious use of blood and blood

titutes. It appears to be generally agreed that does not wait for the appearance of fully developed shock before instituting therapy. One should prevent or treat shock according to the severity of the duration of the operative procedure, the degree of blood loss and the previous condition of the patient rather than wait for an alteration in the concentration of the red corpuscles or for a severe fall in blood pressure. Traumatic shock may develop without any significant alteration in the rate of the pulse or in the concentration of red corpuscles. A decline in the arterial pressure to 60 mm. of mercury is frequently a sign of advanced rather than of early shock. At the beginning of all operative procedures of considerable magnitude a needle should be placed in an accessible vein and fluid should be administered as indicated. The quantity of blood or blood substitute required varies from patient to patient. As Dr. Harkins has said, there is no more logic in giving the same quantity of blood to every surgical patient than there would be in prescribing the same dose of insulin for every patient with diabetes. At any rate, attempts to maintain the blood volume at essentially the normal range during operative procedures have resulted in a widening of the scope of surgery, fewer deaths at the time of operation and a reduction in postoperative complications.

The importance of replacing protein that may be lost in various surgical conditions has received much attention in recent years. Protein deficiencies may be responsible, at least in part, for a number of complications, including wound disruption, abdominal distention, edema, anuria and circulatory failure. The intravenous injection of blood plasma is an efficient method for correcting acute hypoproteinemia, but it is a rather expensive and time-consuming method for giving protein nourishment. With this in mind, Elman⁴ gave a high-protein diet by mouth, but since vomiting frequently rendered this method ineffective he resorted to the use of hydrolyzed protein by intravenous injection. Subsequent work has shown that the principle of introducing the building stores of protein — amino acids and peptides — is sound. This method is now used clinically rather extensively. Although some untoward reactions have been reported and although there are some contraindications to the giving of amino acids intravenously, the results are in general extremely encouraging. Protein deficiencies can be corrected and, more important, they may be prevented by the early administration of an appropriate mixture of amino acids in cases in which adequate amounts of protein cannot be taken by mouth or cannot be assimilated when so taken. This physiologic short cut in protein nutrition, with the addition of water, electrolytes, glucose and vitamins, provides an almost complete intravenous diet. The advantages of the preoperative correction and the postoperative prevention of nutritional disturbances

are obvious; patients can be more adequately prepared for operation and the morbidity and mortality rates can be reduced.

Advances in chemotherapy have had a far-reaching effect on surgery. One cannot help being impressed by the radically altered outlook for patients with septicemia, meningitis, peritonitis and pneumonia that has been effected through the use of sulfonamides and, even more strikingly, that of penicillin. It is difficult in some cases to differentiate the role of chemotherapy and that of transfusions in bringing about this altered picture, because both have played their respective parts, as have better methods of maintaining balance of fluids and electrolytes and nutrition. Now that penicillin has demonstrated its ability to deal with invasive staphylococcal infections, and in view of the promise of still newer antibiotic agents in dealing with infections due to gram-negative bacilli, it seems that in a few years it will be necessary much less often to record a death as having been due to bacterial infection. Such an optimistic statement should probably be followed by an admission of our inability at present to treat effectively by chemotherapy such disorders as chronic ulcerative colitis, regional ileitis, tuberculosis, thromboangiitis obliterans and certain mixed infections of the lung and peritoneum.

Advances in chemotherapy have in no sense lessened the importance of familiarity with and careful observation of certain general practices, such as careful hemostasis and the gentle handling of tissues. It has been shown that infection will develop in wounds even in the presence of potent antibacterial drugs if there exists an unfavorable adjustment of factors concerned in repair. This observation is both an expression of the limitations of the drugs and a warning to the surgeon to observe well-established principles if he wishes to avoid infection. Tissues usually tolerate a moderate degree of contamination if the mechanisms of local resistance are not disrupted by unnecessary damage. The use of agents that suppress bacterial growth has made more evident the importance of a good surgical technic.

If one is to treat the so-called "surgical infections" intelligently, one must differentiate the systemic and local components. The local component is usually characterized at some time in its course by necrosis of tissue. Because integrity of the blood supply is essential for the systemic distribution of the drug to the site of infection, the greatest effectiveness of the agents is observed in treating the invasive types or stages of infection. Under such circumstances the necessity for treatment by operative means may be obviated, but it must be emphasized that the local accumulation of pus should be treated by open drainage. It appears that the use of chemotherapeutic agents has increased the number of cases in which local drainage

only is employed because of the striking reduction in the mortality rate associated with the systemic component of the infection. Thus far, the results that have followed the local use of the various chemotherapeutic agents in the treatment of infected wounds of soft parts and of chronically infected ulcers have not been encouraging.

The problem of operating-room infections continues to be a real one, particularly during the periods when there are many diseases of the respiratory tract. Thanks to the various chemotherapeutic agents, such infections rarely cause death, but they may cause wound disruption and other complications. The work of Hart⁵ and others on the sterilization of air by bactericidal radiation has yielded encouraging results. Perhaps even more practical will be the use of glycol vapors as developed by Robertson⁶ and his associates. Further progress in this important field is awaited with interest.

* * *

The next topic is a consideration of some of the advances in surgery that apply to a particular organ or structure. These will be discussed in a general way, and it is hoped that failure to refer to much important work will be pardoned.

THE ESOPHAGUS

There are few parts of the body — and certainly no part of the intestinal tract — that have presented as many impediments to progress in surgery as has the esophagus. This appears to be mainly due to the fact that the blood supply of the esophagus is relatively poor, that this organ has no serosal covering and that unlike most of the intestinal tract it is a straight tube without a mesentery and without redundancy. Furthermore, it is relatively inaccessible, and the body tolerates infections of the mediastinum extremely poorly.

Carcinoma

A variety of factors in addition to those enumerated above have contributed to delay in advancement in the treatment of carcinoma of the esophagus. The onset may be insidious, and direct extension of the growth or distant metastases may be present before the symptoms cause the patient to consult a physician. The physician himself may not pay sufficient attention to complaints of slight dysphagia or moderate loss of weight. The advanced age of many of these patients has also been a handicap.

Torek⁷ performed a successful resection — without anastomosis — of the midthoracic esophagus for carcinoma in 1913. The patient died of pneumonia thirteen years later. Between 1913 and 1938 a total of thirty-four successful resections of the esophagus for carcinoma were reported by eighteen authors. It is doubtful whether any of these patients lived as

long as five years. The largest series of cases reported by Ohsawa⁸ in 1934. According to Adair^{9, 10} Ohsawa reported four successful resections in cases of carcinoma of the thoracic esophagus, eight successful resections in 14 cases of carcinoma involving the cardia and esophagus, in which 2 to 10 cm. of the esophagus was resected, one successful resection in 5 cases in which 6 to 8 cm. was removed, and two successful operations in which an esophageal jejunostomy was performed.

Since 1938 much attention has been directed to the treatment of carcinoma of the esophagus, and many successful operations have been performed. Except for the problems that are common to the surgery of cancer in general, — namely, those of direct extension and metastasis, — it may be stated that surgery of the lower fourth of the esophagus and cardia has progressed¹¹ in a highly gratifying manner. In other words, satisfactory means are available for removing the lower part of the esophagus and cardia, for mobilizing the stomach and for making an intrathoracic anastomosis of the stomach and the esophagus. To what is this progress due? An occasional advance in surgery can be attributed to a single important discovery, but most of the advances are due to a number of more or less independent observations. Recent progress in surgery of the esophagus fits into this category. Among the many factors that have contributed have been earlier diagnosis as a result of the use of the barium meal and the esophagoscope, better preoperative and postoperative treatment, the more frequent use of transfusions and improvements in technical procedures. The latter include operative details such as the mobilization of the upper end of the stomach, the making of the new anastomosis at a point other than the previous opening and the anchoring of the stomach in the lower part of the chest in order to avoid tension on the suture line of the anastomosis. The experimental observations of Adams and Phemister¹⁰ and of Carter¹² have been particularly helpful in clarifying these points.

Operations on the upper three fourths of the esophagus have been less satisfactory, mainly because of the difficulty in re-establishing the continuity of the alimentary tract. The upper fourth, that part between the base of the neck and the superior surface of the aortic arch, presents an added difficulty in that the proximal esophageal end is so short that the establishment of an external fistula may not be possible. Garlock¹³ has recently reported the result in a patient with carcinoma of the midportion of the esophagus in whom he was able to mobilize the stomach sufficiently to make the anastomosis at a level just below the aortic arch. If one is able to remove the growth and to bring out the upper end of the esophagus, the possibility of connecting this to the stomach by a tube of skin or of rubber always remains, but it is not a desirable type of anastomosis.

ing the last two years Rienhoff¹⁴ has used a variation of the method of Roux¹⁵ in the treatment of carcinoma of the esophagus. The large vessels leading to a segment of jejunum are divided, the superior mesenteric artery, the jejunum is brought across at one point, and the mobilized end is brought through the diaphragm and the chest rather than through a tunnel beneath the skin of the chest wall. In this manner it is possible to obtain enough viable jejunum for replacement of the resected esophagus. Sweet¹⁶ has recently described a modification of the Roux procedure that aids in the mobilization of an undivided segment of the jejunum. This method can be used when the defect that is to be bridged is not so great as that mentioned above.

Esophageal Strictures

Most patients in whom strictures of the esophagus develop as a result of the swallowing of chemicals can be carried along fairly satisfactorily by repeated dilatations. There are some, however, in whom the obstruction becomes complete. One of the main difficulties in esophageal reconstruction from whole intestine is the appearance of fistulas at the point of anastomosis of the skin with the esophagus or the stomach, particularly the latter. Additional disadvantages are the multiple operative procedures that are necessary in order to complete the tube of skin and the absence of peristalsis. Other measures that have been used in the making of an artificial esophagus include the placing beneath the skin of the anterior chest wall of a mobilized loop of the colon, the greater part of the mobilized stomach or a gastric tube that is constructed from the greater curvature of the stomach. The various methods are reviewed in an excellent article by Ochsner and Owens.¹⁷ Yurasov¹⁸ has stated recently:

The brilliant idea formulated by Roux and Gerzen of substituting a mobilized segment of the jejunum for the original, useless esophagus was first put into practice by Gerzen in 1908, but found few adherents because of the high incidence of necrosis in the mobilized jejunal loop. Slight changes in this technique introduced by Lexer in 1911 to a very large degree obviated this danger.

Lexer¹⁹ brought the jejunal loop up to the mid-portion of the anterior wall of the chest and employed a short tube of skin leading to the cervical esophagus. This technic has been until recently the procedure of choice in the creation of any artificial esophagus. Because of the multiple stages necessary, because of ulcers at the junction of skin and mucous membrane and because of the absence of peristaltic movement in the skin tube, Yudin has abandoned the Lexer technic and has modified slightly the original Roux procedure.

The technic of Yudin²⁰ has not been described in detail; but it is essentially the Roux procedure. A section of jejunum 30 to 40 cm. in length is mobilized by dividing the vascular pedicle near the root of the mesentery. At a second stage the jejunum is divided proximally and the end of the mobilized

section is placed in a tunnel beneath the skin of the anterior chest wall that extends to the mandible. At this or a subsequent operation the jejunum is anastomosed to the side of the esophagus at a level just above the clavicle. Regarding the results Yurasov,¹⁸ Yudin's associate, stated: "We have performed thirty-eight esophagoplasties by bringing the jejunum up to the clavicle. In 14 of these cases the cervical segment of the esophagus was anastomosed with the jejunum. . . . We lost only 4 of our 38 patients."

Yudin's success may be explained in part by the fact that he was dealing with a benign lesion and that it was not necessary to divide the esophagus. As stated previously, the jejunum is anastomosed to the side of the undivided esophagus. It has been found by a number of observers that complete obstruction of the esophagus of dogs produces death in from one to three days. An entirely adequate explanation for this has never been advanced, but it is certain that both man and dog tolerate poorly division of the upper part of the esophagus.

Atresia

Congenital atresia of the esophagus with tracheoesophageal fistula has presented one of the most difficult problems in surgery. An illustration of this is presented in the report of Lanman²¹ of 32 patients with congenital atresia of the esophagus who were treated in the Children's Hospital in Boston. He stated: "In spite of the fatal outcome in all the 30 operative cases, it is felt that considerable progress along rational lines is being made. The successful operative treatment of a patient with this anomaly is only a question of time." It is only recently that the results have become encouraging. It has been almost five years since Leven performed the first of a number of operations on an infant with atresia who is now alive and well. Ladd²² has a total of 13 infants with congenital atresia of the esophagus who are alive, the oldest of these being four and a half years of age. Haight²³ has had remarkable success with the use of the ideal plan of extrapleural ligation of the fistula and primary anastomosis of the esophageal segments. This procedure was feasible in 17 of 24 infants in whom an exploration of the anomaly was performed. Six of the 16 patients in whom a primary anastomosis was performed are living from four and a half months to three years after operation, and all feedings are swallowed through the reconstructed esophagus. Several other surgeons, including Daniel,²³ have had success in a smaller number of patients.

It is likely that time and additional experience will show that primary anastomosis as used by Haight is the procedure of choice in those patients in whom the two ends of the esophagus can be brought together. On the other hand, improvements in methods for creating an artificial esophagus may point to the simpler procedure of bringing out

the upper and lower segments at the first operation under local anesthesia and subsequently performing a plastic procedure. The problem will probably be one of evaluating a higher earlier mortality rate associated with primary anastomosis as compared with a poorer functional result accompanying a delayed plastic procedure.

SURGERY OF THE LUNGS

Advances in surgery of the lungs have proceeded at a rapid pace, and no attempt will be made to consider them in detail. The increased use of the roentgen rays, lipiodol injection and the bronchoscope has resulted in earlier and more accurate diagnosis. Included among the functional tests that have been brought to a greater degree of perfection is bronchspirometry, by which the respiration of each lung can be measured.

Bronchiogenic carcinoma constitutes approximately 8 per cent of all carcinomas. It is only eleven years since the first one-stage removal of an entire lung was performed by Graham.²⁴ Shortly after this pneumonectomy for carcinoma, Rienhoff²⁵ removed an entire lung in a child. Graham²⁶ stated recently:

Rienhoff early demonstrated by his first case, in which the operation was carried out at almost the same time as my first case, that it is not necessary to perform a thoracoplasty in order to obliterate the pleural space and that individual ligation of hilar structures with a careful suturing of the bronchus has many advantages over the mass ligation of the hilar pedicle. These principles have now been generally accepted as procedures of choice. Total pneumonectomy, therefore, today usually means an operation for the complete removal of a lung, performed in one stage and with individual ligation of hilar vessels and suturing of the bronchus.

As is true in most well-conceived operative procedures, there has been a steady decline in the mortality rate associated with total pneumonectomy. At least part of this reduction is due to a realization of the futility of such an extensive procedure if there is much involvement of the mediastinal nodes, if there is bloody pleural fluid or if the phrenic or recurrent laryngeal nerve is paralyzed. Graham²⁶ has had a series of 104 patients in whom total pneumonectomy was performed, eighty-one of the operations being for neoplasms. The mortality rate in his last seventy cases for malignant neoplasms has been 30 per cent and that in the last 25 cases 12 per cent. Rienhoff²⁷ has performed eighty-six total pneumonectomies, sixty-four of which were for bronchiogenic carcinoma. His mortality rate during the last several years has been 12 per cent.

Total pneumonectomy has now been performed many times by many surgeons. Of greater importance than the steady reduction in the operative mortality rate is the fact that a number of the patients have shown no evidence of extension or metastasis. Furthermore, ordinary activities are very little restricted.

In a recent impressive personal experience, a right total pneumonectomy was performed for a large pulmonary metastasis that was detected more than four years after resection of the large bowel for carcinoma. The convalescence was uneventful and the patient left the hospital two weeks after the operation. He returned to work, but pneumonia developed in the remaining left lung four months after operation. This responded rapidly to sulfonamide therapy, and the patient left the hospital after a stay of one week. He returned to work one week later and has done well during the last three months. There has been a gain in weight of 11 pounds since the operation. When one recalls that it was twenty-five years after Billroth performed the first partial gastrectomy for cancer of the stomach before the procedure received any great attention, it is remarkable how rapidly and how widely total pneumonectomy has been accepted.

Suppurative disease of the lung and bronchiectasis in particular have constituted the most frequent single indication for lobectomy. The reduction in the mortality rate in recent years has been highly gratifying. Probably the chief factor in this reduction has been replacement of the massive hilar ligature by individual ligation of the vessels and a careful closure of the bronchus. A forward step was taken by Nelson,²⁸ by Churchill and Belsey²⁹ and by others when it was suggested that the bronchopulmonary segment should replace the lobe as the surgical unit of the lung. Probably everyone will agree that the removal of the diseased part should be accompanied by the conservation of as much normal pulmonary tissue as possible. Progress has also been made in the surgical treatment of other types of suppurative disease. An increasing number of chronic lung abscesses are being treated by lobectomy or pneumonectomy. Some cases of recurring unilateral pneumonitis and of lipoid pneumonia may be relieved by the same means. If congenital cystic disease is localized, the treatment consists of resection, preferably before infection has occurred. More than a year ago I performed a two-lobe lobectomy on the right side for congenital disease in an infant two months of age, and the result has been highly gratifying. It is the opinion of Gross³⁰ and of others that young children tolerate pulmonary resection satisfactorily.

One of the most important advances in the treatment of tuberculosis has resulted from an appreciation of the frequency of tracheobronchial infection and from the realization that this should be treated before collapse measures are employed. The indications for collapse therapy have been gradually extended and any patients who would previously have been treated by pneumothorax therapy are now being treated by thoracoplasty. The most significant recent change, however, has been in the increase in popularity of lobectomy and pneumonectomy in the treatment of pulmonary tuber-

is. Most of the early operations of this type performed because of a mistake in diagnosis. It was observed that many of the patients treated, surgeons were encouraged to use this method of therapy in treating certain patients with tuberculosis. Dolley and Jones³¹ stated in 1940 there is a definite place for lobectomy in certain cases and probably a place for pneumonectomy in a small group of cases. The main indications for these procedures have been considered to be the presence of strictures of bronchi that prevent adequate aeration and drainage, thick-walled uncolapsible cavities and tuberculous bronchiectasis. Churchill and Klopstock³² have recently reported cases in which patients with tuberculosis were treated by lobectomy. In 3 of these the orthodox indications for resection were present, whereas in the remaining 3 the usual indications for thoracoplasty existed but lobectomy was performed instead. Healing per primam occurred in all cases.

Churchill and Klopstock³² stated:

Lobectomy provides a more selective and immediate method of eradicating certain lesions of tuberculosis than does collapse therapy. It may be used subsequent to artificial pneumothorax, thereby restoring to that procedure the reputation of finesse that it should enjoy. A method of treatment that combines conservation of lung function, with immediate conversion of the sputum, and a shortening of the span of treatment cannot be dismissed until its scope has been more fully explored.

These authors,³² who make a sharp distinction in the indications for lobectomy and for pneumonectomy in the treatment of tuberculosis, write:

At the present time, total pneumonectomy cannot be considered an alternative to collapse therapy provided that collapse therapy is applicable to the case under consideration. It is both irreversible and nonselective. It irrevocably and seriously limits any therapeutic procedure that may be needed for the lung of the contralateral side. Circumscribed by strict indications, total pneumonectomy in tuberculosis may be a lifesaving operation when no other procedure is feasible. Lobectomy, on the other hand, is proposed as a highly selective measure for dealing with certain unilateral lesions. It is, indeed, far more conservative of pulmonary functions than even a seven-rib thoracoplasty.

During the last two years Overholt³³ in a few cases has deliberately elected pulmonary resection in preference to thoracoplasty. He has this to say regarding the use of lobectomy and pneumonectomy in the treatment of tuberculosis:

It can be definitely stated that the tuberculous subject and a patient with a positive sputum does not introduce any particular or unique hazards in regard to tissue healing. We can also state with certainty that the matter of resecting a tuberculous lung presents no unusual technical problem if the procedure is carried out as a primary form of treatment. The dissection of the hilum is carried out with probably greater ease than the dissection of the hilum in patients with suppurative disease or tumor. The problem of preventing contralateral spread still bothers us.

Overholt is of the opinion that pulmonary resection will not come to occupy so prominent a place in the treatment of tuberculosis as does pneumothorax

therapy or thoracoplasty. During a ten-year period he³³ and his associates have selected 94 patients in whom pulmonary resection was carried out, whereas well over 2000 patients have been treated by thoracoplasty during the same period. In 1942 and 1943 Overholt performed pulmonary resections on 59 patients with tuberculosis, with a mortality rate of 13 per cent. Pneumonectomy was performed in the majority of the cases. Since poor-risk patients were included, this accomplishment is an enviable one.

It is unnecessary to point out that the use of pulmonary resection in the treatment of pulmonary tuberculosis is in a formative stage. It is my opinion that the indications for resection are being extended too rapidly.

(To be concluded)

EDITH E. PARRIS, *Assistant Editor*

CASE 30331

PRESENTATION OF CASE

A twenty-four-year-old man entered the hospital because of shortness of breath, chest pain and inability to swallow.

The patient satisfactorily passed the Army induction examination twenty months before entry, but was discharged five months later. Eight months prior to admission, on examination for re-entrance into the Army, he was told that the x-ray films showed a tumor in the mediastinum. At that time he was asymptomatic, but within the next two months he noted a dull substernal pain on turning his head to one side and easy fatigability. He had considerable trouble swallowing solids, and moderate trouble with liquids. He developed a sensation of fullness in the throat and shortness of breath on exertion. One month before entry the substernal pain increased in frequency and severity, but still did not bother him especially. He had lost 20 pounds in eight months.

For eight years he had had a persistent hoarse voice, which he first noted following a sore throat. He had had occasional head colds and cough productive of whitish phlegm for several years.

Physical examination showed a well-developed, well-nourished man in no distress. The voice was hoarse, and there was an occasional cough. The heart and lungs were normal. There was no tracheal tug or increase in the mediastinal dullness. Moderate costovertebral-angle tenderness was present, but the abdomen was otherwise negative.

Laryngeal examination showed normal movement of the arytenoids and of the vocal cords. The cords did not completely occlude on adduction. There was slight thickening of the upper surface of the left cord, which prevented the cords from coming together. No evidence of active paralysis, any growth or tuberculosis was seen.

The blood pressure was 104 systolic, 46 diastolic, on the right, and 124 systolic, 60 diastolic, on the left. The temperature, pulse and respirations were normal.

Examination of the blood showed a white-cell count of 5800, with 70 per cent neutrophils. The

hemoglobin was 14.5 gm. per 100 cc. The urinalysis was normal. A blood Hinton test was negative.

X-ray examination of the chest showed the lungs to be clear throughout. The heart was normal in position, and the aortic knob was not visible in the posteroanterior projection. On the left side the hilar shadow was prominent, owing to a well-defined, round, soft-tissue mass measuring 3 cm. in diameter (Fig. 1). In the lateral and oblique views it appeared to be close to the aortic arch. Fluoroscopically it did not seem to pulsate. No displacement of the esophagus was seen. A barium swallow showed no delay in passage, and the outline of the esophagus was normal. Lateral films of the chest revealed the mass to lie just to the left and slightly anterior to the spine in relation to the descending aorta.

On the sixth hospital day an operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. MERRILL C. SOSMAN†: The history makes one think immediately of mediastinal tumor, particularly with the report from the Army induction center that the x-ray films showed a tumor in the mediastinum. From what we see in the x-ray films the findings are out of proportion to the symptoms that this man presented. It is perfectly possible that a large part of these symptoms recorded were due to the fact that he was told at the induction center that the x-ray showed a tumor of the mediastinum. In other words, the dull substernal pain, the easy fatigability and the trouble with swallowing could all have been caused by pure nervousness, a psychologic upset because someone had told him that he had a tumor in the mediastinum. Aside from that I do not believe the history gives much of a lead. Occasionally, of course, a history alone makes the diagnosis. A classic example of that is angina pectoris. In fact, that is the only way one can make the diagnosis of angina pectoris in the majority of cases.

The physical examination is of no help. It was entirely negative except for the blood pressure, which was definitely lower on the right than on the left. I should like to know whether that was repeated and confirmed or whether it was a single observation.

DR. BENJAMIN CASTLEMAN: It is the only one recorded.

DR. SOSMAN: It is perfectly possible on a single examination to get a lower pressure on one side than on the other, again owing to psychic stimulus. The pain of pressure on one arm could excite the patient and give a higher reading in the second arm. A discrepancy of this sort should be checked and verified two or three times or on successive dates. This was only a single observation so far

†Roentgenologist, Peter Bent Brigham Hospital, clinical professor of roentgenology, Harvard Medical School

can tell, and it was the only positive physical finding in the entire examination. I doubt if the thickening of the upper surface of the left cord had any relation to the disease in this chest and I also doubt if the little lesion was seen in the x-ray examination was the cause of all the symptoms that are described. I would rather attribute these symptoms to nervous-

ness and worry in a man who had been told that he had a mediastinal tumor.

cannot be sure of the tumor shadow in the lateral and oblique views. It was probably observed and located fluoroscopically; by rotating the patient one can tell by the angle of disappearance how far forward or posteriorly the shadow is.

Can you see it any better than I can, Dr. Robbins?

DR. LAURENCE L. ROBBINS: I cannot see it anywhere except in the anteroposterior film. I think

FIGURE 1

So far as these x-ray films are concerned, I must frankly admit that I had great difficulty in locating the small mass described in the lateral and oblique views. The anteroposterior view on fairly close scrutiny shows a normal chest, a small heart and a prominent pulmonary artery, which is seen in a great many individuals with ptotic hearts.

There is a little extra added here in the way of a double curve just below the pulmonary artery on the left border, projecting out in the region of the root of the left lung — a shadow that is about 2 cm. in width and 4 to 5 cm. in length. I stopped in the X-ray Department on my way over to see if Dr. Robbins could show the mass to me and he admitted that he could not see it. I frankly admit that I

that the statement must have been based on a fluoroscopic observation.

DR. SOSMAN: It is stated: "On the left side the hilar shadow was prominent, owing to an ill-defined, round, soft-tissue mass measuring 3 cm. in diameter. In the lateral and oblique views it appeared to be close to the aortic arch. Fluoroscopically it did not seem to pulsate. No displacement of the esophagus was seen. A barium swallow showed no delay in passage, and the outline of the esophagus was normal." The last statement indicates a rather striking discrepancy from the recorded symptoms of difficulty in swallowing, particularly the swallowing of solids.

The history certainly suggests a mediastinal tumor. The x-ray examination shows a very small, rather indeterminate shadow in the region of the

root of the left lung. It is hard to conceive how a shadow of that size and in that location could have given these symptoms. It is almost impossible to attribute the difference in blood pressure in the two arms to a small tumor in that location. If that discrepancy was real and not a faulty observation, one has to assume that it was caused by something else, perhaps a congenital anomaly of the blood vessels.

The possibilities in the way of diagnosis are legion. I do not know of any group of diseases that is more complex or variable than that of mediastinal tumors. These are divided into seven groups.

The first group comprises lymph nodes, the two main divisions being the inflammatory group and the neoplastic group, the latter primary and metastatic. The primary lesions, of course, are the malignant lymphomas. I do not believe that we can call these lymph nodes, either by their location or by their distribution. The patient had no evidence of infection to go with such a thing as tuberculosis or fungus infection or the nonspecific infections of lymph nodes. So I think we can rule out the lymph nodes, which are the commonest group of mediastinal tumors.

The second group consists of primary tumors of the mediastinum. The dermoids and the teratomas are nearly always in the anterior mediastinum. They are smooth, round, quite distinct in outline and quite unlike the appearance in this case. The ganglioneuromas and neurofibromas are usually posterior and arise from the intercostal nerves. Again, they are in a different location and have a different x-ray appearance from the shadow we see here. Occasionally we find the rare types, — the lipomas, the fibromas, the chondromas and even the cystic tumors (hygromas or lympho-angiomas), — none of which fit this particular picture.

The third group, infections in the mediastinum, I believe is ruled out. There is no evidence in the history or in the x-ray examination of an inflammatory process.

The thyroid tumors and thymomas come together in a single group. They are nearly always in the anterior and upper portions of the mediastinum, although they are occasionally found in the middle third, even as far down as the diaphragm, and are rarely found as an aberrant thyroid gland anywhere in the mediastinum.

Tumors of the esophagus, either the mucosal tumors or the extramucosal tumors of the esophageal wall, must be considered, although the fluoroscopist said that the esophagus was not displaced and there was no delay in the swallowing of barium. They most frequently occur in the middle third of the posterior mediastinum and sometimes have a slight attachment to the esophageal wall, and that slight attachment may be capable of causing symptoms without showing anything in the

x-ray examination in the way of a filling defect obstruction.

The tumors of the heart and aorta are next. I can rule out aneurysms and various tumors of the pericardium itself.

That leaves the bronchi as the only remaining source of origin for this tumor. We can rule out primary tumors of the bronchi. They are usually intrabronchial, and cough is the chief symptom. The patient's age is against it. He had no atelectasis, and no history of the raising of bloody sputum. In other words, all the symptomatology of carcinoma of the bronchus is missing, which does not rule it out to be sure, but is strongly against it. There are also the tumors that Dr. Robbins has described, bronchiogenic cysts, apparently embryonic tumors that develop cysts. These nearly always have smooth, round, distinct outlines, whereas this tumor, as I see it, has a serrated lobular outline. Then there is what has been called a "hamartoma," a fascinating tumor that I spring on every possible occasion to show my erudition. It is a congenital rest or bud, and in this particular case, a lung bud, presumably an aberrant lobe with undeveloped, collapsed lung containing recognizable lung tissue; it may become cystic, the cavity being lined with pulmonary or bronchial epithelium. Hamartomas and bronchial cysts overlap: some pathologists call them one thing and still others call them another, although "hamartoma" may be considered the basic classification for the entire group.

I shall summarize by saying that this patient had a small indefinite mediastinal mass. Since I have ruled out most of the possibilities that I had listed, I suggest that it was either one of the bronchiogenic cysts (hamartoma) or one of the duplications of the gastrointestinal tract, a cyst attached to the esophagus. I rather favor the former because fluoroscopy showed nothing in the esophagus. I should be interested to know what the x-ray interpretation was.

DR. CASTLEMAN: Dr. Davis's interpretation on fluoroscopy was that it had the appearance of an enlarged lymph node, fitting in with the first of your seven groups.

CLINICAL DIAGNOSIS

Neurofibroma of posterior mediastinum.

DR. SOSMAN'S DIAGNOSIS

Hamartoma of left lung (undeveloped lung bud).

ANATOMICAL DIAGNOSIS

Sarcoid of mediastinal lymph nodes.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: I am sorry that Dr. Sweet is not here to describe the operative findings. His

eads: "One large, irregular, dark gray mass was removed from under the arch of the and another, measuring 2 by 3 cm., from the e above the arch of the aorta. Two other nodes' were left behind." Apparently the first that Dr. Sweet refers to is that represented shadow with the serrated border indicated by row in the roentgenogram of the chest (Fig. 1). Microscopic examination showed that these s were lymph nodes almost completely red by sarcoid.

I suppose that it is quite possible that the films by the Army showed a larger mass and that e time of operation the sarcoid was in the ss of regression. We know that in most cases sarcoid the mediastinal nodes regress after a od of time; there is another group, however, progress to involve the lung parenchyma itself. general belief is that the mediastinal nodes be e involved first and that involvement of the ; parenchyma is secondary. One ordinarily ks of enlarged lymph nodes as being secondary : neighboring lesion but a great many cases have n reported, especially from Sweden,² and we e had several here, that showed primary enge- ment of hilar nodes followed by parenchymal ase. Has that been your experience, Dr. Sosman?

DR. SOSMAN: Yes; first the hilar nodes, and then rograde lymphatic spread into the lungs.

DR. CASTLEMAN: The same principle of retro- de lymphatic spread probably occurs in metas- ic carcinoma to the mediastinal nodes from cer of the stomach or other extrapulmonary cinomas. In other words so-called "lymphatic ead" of pulmonary metastases may begin in the ph nodes and extend into the lung parenchyma her than drain from the lung into the lymph les.

Dr. Ronald C. Sniffen has recently reviewed our es of metastatic pulmonary carcinoma with H. P. Mueller of the X-ray Department.³ They lieve that the lymphatic spread of carcinoma has characteristic x-ray pattern and that in many es it develops by retrograde extension from the ar lymph nodes.

DR. SOSMAN: We have seen it occasionally, but is rare.

Do you believe that this small group of lymph des involved with sarcoid could have accounted r all this patient's symptoms.

DR. CASTLEMAN: No, unless they were larger one time. It would be interesting to find out hether the blood-pressure readings were repeated d found to be different on the two sides. I do not lieve that pressure on the vessels by these nodes ould have caused a difference in the blood pressure the two arms.

DR. SOSMAN: The most striking thing about roid, in my experience, and a valuable point in aking the diagnosis, is the marked discrepancy tween the extensive pulmonary involvement,

including the hilar and mediastinal nodes, that is usually present and the paucity of symptoms. Patients do not have symptoms with sarcoid. Here there was slight involvement and marked symptoms. The symptoms suggest that he was worried about his condition.

DR. JOSEPH C. AUB: Was the plasma protein ever determined?

DR. SOSMAN: And the globulin?

DR. CASTLEMAN: No. It would also be interesting to know the results of a tuberculin test.

CASE 30332

PRESENTATION OF CASE

A seventy-seven-year-old retired domestic entered the hospital because of hemoptysis and sudden chest pain.

The history was quite inadequate. The patient had apparently been in good health until two or three months prior to entry, at which time she complained of dull pain in the lower right chest. She was apparently able to carry on until two days before entry, when she experienced a sudden "crack" in the region of the lower right costal margin. This was followed by pain that persisted, according to the record, "as a severe episodic form of pain exaggerated by respirations." She developed a cough productive of blood-streaked or rusty sputum. The abdomen became distended, and swelling of the ankles developed. She was unable to sleep or eat. She had no true chills but several "sieges of trembling."

The past history was essentially negative. She had slept on two pillows all her life.

Physical examination showed an emaciated, cyanotic, dehydrated woman. The skin was warm and dry. The lips and tongue were dry. Chest expansion was poor on the right with dullness and decreased breath sounds, voice sounds and tactile fremitus over the lower half. Coarse moist rales were heard over the upper half of both lungs. The heart was of normal size. The sounds were of fair quality, and there were occasional extrasystoles. The abdomen was distended and taut. Slight pitting edema of the ankles was noted.

The blood pressure was 120 systolic, 60 diastolic. The temperature was 104°F., the pulse 130, and the respirations 30.

Examination of the blood showed a red-cell count of 4,050,000, with 13.9 gm. of hemoglobin. The white-cell count was 21,800, with 88 per cent neutrophils, of which 80 per cent were band forms and 8 per cent myelocytes. There was marked

CLINICAL DIAGNOSIS

Lobar pneumonia.

DR. HARWOOD'S DIAGNOSIS

Carcinoma of bronchus, with secondary pneumococcal infection.

ANATOMICAL DIAGNOSES

Lobar pneumonia (Friedländer's bacillus).

Bacteremia (Friedländer's bacillus).

Duodenal ulcer, acute.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy we found about 100 cc. of turbid fluid in the right pleural cavity and a similar amount on the left side. The mass seen by x-ray proved to be a consolidated right lower lobe which on section was soft and brownish gray and on scraping the surface a large amount of mucoid material was obtained. Cultures from the lung and heart's blood showed the typical mucoid Friedländer's bacillus. The fact that the patient died twenty-four hours after admission, two days after

the onset of symptoms, fits in with the usual course of the Friedländer type of pneumonia. Most of the patients die within a few days, although a few develop abscesses and have recurrent attacks of pneumonia. We were unable to find an encapsulation of the fluid, although there were some old adhesions on the right side. The cause of the positive guaiac test on the stools was a small duodenal ulcer.

DR. SOSMAN: That round shadow is the apex of the consolidated right lower lobe?

DR. CASTLEMAN: I should think so.

DR. HARWOOD: What did the ante-mortem culture show?

DR. CASTLEMAN: Friedländer's bacillus, but growth had not occurred until after the patient's death. In retrospect, the organisms seen by the house officer were Friedländer's bacilli, which are gram negative, not pneumococci, which are gram positive.

DR. HARWOOD: I had considered Friedländer's pneumonia because in that condition death is usually early and distention of the abdomen is a prominent feature, but ruled out the diagnosis because of the bacteriologic findings that were reported.

PRESCRIPTION OF HEAVY CREAM

LAST week the *Journal* took editorial notice of one of the more recent *causes célèbres* — Amendment 2 to War Food Order 13, emanating from the Office of Distribution of the War Food Administration. According to this amendment, medical prescriptions for heavy cream must be approved by the public-health officer or the secretary of the county medical society of the area where a patient or hospital is situated.

In Massachusetts, authority has been given to the district supervisor of the Office of Distribution to make a reasonable interpretation of the terms of the amendment, to the extent that not only will

the broad purposes of the order be better served but practicing physicians will be relieved of the irritation of having their prescriptions subject to the endorsement of a variety of persons. The endorsing function has, by this interpretation, been vested in an advisory committee composed as follows: John H. Sullivan, district supervisor, Office of Distribution, War Food Administration, chairman; Dr. Vlado A. Getting, commissioner of public health, Commonwealth of Massachusetts; Dr. G. Lynde Gately, health commissioner, City of Boston; Dr. H. Quimby Gallupe, secretary, Board of Registration in Medicine; Dr. Nathaniel W. Faxon, director, Massachusetts General Hospital; and Drs. F. Gorham Brigham, Joseph Garland, Loring Grimes and Franklin W. White, representing the Massachusetts Medical Society.

Prescriptions, which are valid for a period not exceeding sixty days, should indicate the date of issuance, the butter-fat content required, the daily quantity required and the necessity of such cream for medical treatment, and should be forwarded to the War Food Administration, 404 Park Square Building, Boston. Telephone inquiries should also be directed to the Food Distribution Administration (LIBerty 7520).

It is apparent that few prescriptions will receive the endorsement of this committee in view of the overwhelming mass of evidence that cream in excess of 19 per cent butter fat is rarely, if ever, a necessity in medical treatment. Milk, in these critical days, needs to be conserved. One of the best ways of conserving it in order that we may have enough fluid and dried milk, butter, cheese and light cream, is practically to abolish, for the time being, the luxury of heavy cream.

An appeal to the patriotism of patients should be almost sufficient to eliminate the demand for heavy cream.

RED-CELL RESIDUES

THE organization and rapid growth in the last three years of the Blood-Donor Service of the American Red Cross has been one of the miracles of this country's ability to produce for war. During the interval between the two world wars it became evident that restoration of blood volume with plasma

CLINICAL DIAGNOSIS

Lobar pneumonia.

DR. HARWOOD'S DIAGNOSIS

Carcinoma of bronchus, with secondary pneumococcal infection.

ANATOMICAL DIAGNOSES

Lobar pneumonia (Friedländer's bacillus).

Bacteremia (Friedländer's bacillus).

Duodenal ulcer, acute.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: At autopsy we found about 100 cc. of turbid fluid in the right pleural cavity and a similar amount on the left side. The mass seen by x-ray proved to be a consolidated right lower lobe which on section was soft and brownish gray and on scraping the surface a large amount of mucoid material was obtained. Cultures from the lung and heart's blood showed the typical mucoid Friedländer's bacillus. The fact that the patient died twenty-four hours after admission, two days after

the onset of symptoms, fits in with the usual course of the Friedländer type of pneumonia. Most of the patients die within a few days, although a few develop abscesses and have recurrent attacks of pneumonia. We were unable to find an encapsulation of the fluid, although there were numerous old adhesions on the right side. The cause of the positive guaiac test on the stools was a small acute duodenal ulcer.

DR. SOSMAN: That round shadow is the apex of the consolidated right lower lobe?

DR. CASTLEMAN: I should think so.

DR. HARWOOD: What did the ante-mortem culture show?

DR. CASTLEMAN: Friedländer's bacillus, but growth had not occurred until after the patient's death. In retrospect, the organisms seen by the house officer were Friedländer's bacilli, which are gram negative, not pneumococci, which are gram positive.

DR. HARWOOD: I had considered Friedländer's pneumonia because in that condition death is usually early and distention of the abdomen is a prominent feature, but ruled out the diagnosis because of the bacteriologic findings that were reported.

DESCRIPTION OF HEAVY CREAM

LAST week the *Journal* took editorial notice of one of the more recent *causes célèbres* — Amendment 2 to War Food Order 13, emanating from the Office of Distribution of the War Food Administration. According to this amendment, medical prescriptions for heavy cream must be approved by the public-health officer or the secretary of the county medical society of the area where a patient or hospital is situated.

In Massachusetts, authority has been given to the district supervisor of the Office of Distribution to make a reasonable interpretation of the terms of the amendment, to the extent that not only will

the broad purposes of the order be better served but practicing physicians will be relieved of the irritation of having their prescriptions subject to the endorsement of a variety of persons. The endorsing function has, by this interpretation, been vested in an advisory committee composed as follows: John H. Sullivan, district supervisor, Office of Distribution, War Food Administration, chairman; Dr. Vlado A. Getting, commissioner of public health, Commonwealth of Massachusetts; Dr. G. Lynde Gately, health commissioner, City of Boston; Dr. H. Quimby Gallupe, secretary, Board of Registration in Medicine; Dr. Nathaniel W. Faxon, director, Massachusetts General Hospital; and Drs. F. Gorham Brigham, Joseph Garland, Loring Grimes and Franklin W. White, representing the Massachusetts Medical Society.

Prescriptions, which are valid for a period not exceeding sixty days, should indicate the date of issuance, the butter-fat content required, the daily quantity required and the necessity of such cream for medical treatment, and should be forwarded to the War Food Administration, 404 Park Square Building, Boston. Telephone inquiries should also be directed to the Food Distribution Administration (LIBerty 7520).

It is apparent that few prescriptions will receive the endorsement of this committee in view of the overwhelming mass of evidence that cream in excess of 19 per cent butter fat is rarely, if ever, a necessity in medical treatment. Milk, in these critical days, needs to be conserved. One of the best ways of conserving it in order that we may have enough fluid and dried milk, butter, cheese and light cream, is practically to abolish, for the time being, the luxury of heavy cream.

An appeal to the patriotism of patients should be almost sufficient to eliminate the demand for heavy cream.

RED-CELL RESIDUES

THE organization and rapid growth in the last three years of the Blood-Donor Service of the American Red Cross has been one of the miracles of this country's ability to produce for war. During the interval between the two world wars it became evident that restoration of blood volume with plasma

or serum was the *sine qua non* of the treatment of shock, and the large supply of plasma now available to our armed forces is the result of careful and long-sighted planning.

During the course of World War II interest has been aroused in some of the constituents of the blood other than plasma itself. This has been true of the red-cell residues following the removal of plasma from a blood donation. Soon after the organization of the Blood-Donor Service it became apparent that the loss of red-cell residues was a frank waste of an important part of the donor blood. Furthermore, as experience with war casualties grew, a need for the red-cell component of blood, as well as the plasma, became evident. Red cells have been supplied so far to our troops overseas by whole blood drawn for the purpose at the time and place it was to be used. The use of red-cell residues at the front has been limited by the poor storing qualities, so that even with air-borne transportation it has not been practical to use them.

Red-cell residues have been made available, however, to certain hospitals in the United States for civilian use. Taylor, Thalhimier, and Cooksey¹ report the administration of eighteen thousand transfusions using red-cell residues resuspended in physiologic saline solution. Their work has confirmed, on a much larger scale, the experience of many others who have in recent years shown that suspensions of red cells may, with certain limitations, be used in the treatment of anemia.

The red-cell suspensions so used furnish all the important elements for the replacement of erythrocytes. The chief advantage of their use is that the plasma is saved for other purposes. Another advantage is that, by suspending the erythrocytes in a smaller amount of fluid than that necessary to restore the original volume, a transfusion medium is made that contains less sodium chloride and more hemoglobin than a whole-blood transfusion. This procedure is particularly useful in patients with severe anemia and congestive cardiac failure, in whom it is urgently desirable to raise the hemoglobin and red-cell count and to reduce the blood volume and body salt. Red-cell suspensions made in this way, however, remain usable for a much

shorter period of time than those resuspended their original volume in physiologic saline solution or in one of the newer fluids.

The storage of red-cell suspensions has been studied for a number of years, but research has been greatly stimulated by the quantities now available as well as by the possibility that, with air-borne transportation, the cells might be used by the armed forces overseas if their life in storage could be prolonged. Investigators have been searching for the ideal resuspending fluid — one that would prevent increased fragility of the cells to hypotonic solutions, that could be given without fear of untoward reaction and that would, if possible, promote the longevity of the cells after administration. Solutions containing various combinations of electrolytes, and usually glucose, have been extensively studied regarding both the prevention of hemolysis in vitro and the duration of life of the cells in vivo. Denstedt et al.,² after much painstaking work, proposed a fluid containing 2.3 per cent glucose and 1.7 per cent sodium citrate, buffered to pH 7.4 with sodium phosphate. Using red cells tagged with radioactive iron, Ross³ and others⁴ have found that cells resuspended in Denstedt's fluid, or a similar mixture, can be stored for two weeks, or perhaps longer, with 80 to 90 per cent of the cells surviving forty-eight hours after transfusion. Although further studies are necessary, this is an indication of the possibilities of the use of red-cell suspensions.

The separation of blood into its physiologically active components offers new opportunities for the blood bank of the future. One might think of each community with a blood-donor service prepared to supply whole blood, plasma, albumin, specific globulin fractions and erythrocyte suspensions. The proper use of such a service would require the cooperation of the physicians within the community, but the therapeutic possibilities are manifold.

MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE TO AID THE DISTRICT
RATIONING OFFICER

MEDICAL RESPONSIBILITY IN FOOD RATIONING

The need for some system of food rationing made itself felt in the first year of war, when it became apparent that shortages of certain foods would give rise to inequalities of distribution and resultant hoarding, and might even cause their disappearance from the market. These shortages were due to two obvious causes—a tendency to decreased production as a result of insufficient labor and material, and an increased consumption because of the growth of the armed services and the demands of lend lease. On March 1, 1943, consequently, some months after sugar rationing had been put into effect, a point system of rationing for many meats, fats and processed foods was established.

Rationing under any circumstances is subject to difficulties: man is ever mindful of his own, and war always presents the contrasts of great sacrifices and great selfishness. In this country its difficulties are increased by the peculiarities of our national situation. We are a food-producing country, with a fixed population of diverse dietary habits. Seasonal differences in food supply exist, making uniform rationing regulations inconsistent, and we have experienced, on the home front, an almost complete immunity to the perils of war.

Nevertheless, even with the relatively mild degree of food rationing to which we have so far been subjected, there was early recognized the possible need for special consideration of certain patients and institutions on account of health requirements, in order to safeguard in theory, and in practice so far as possible, the rights of all. Consequently in April, 1943, the director of the War Food Administration requested the National Research Council to appoint "a group of nationally known physicians to advise the War Food Administration concerning the extent of these special needs and the best method of meeting them."

The Subcommittee on Medical Food Requirements of the Committee on Drugs and Medical Supplies within the Division of Medical Sciences of the Council resulted. This committee studied the problem during the next few months, and published its report in the October 16 issue of the *Journal of the American Medical Association*.

The recommendations of this report form the basis on which departures from strict adherence to food rationing are made on medical grounds. They limit and interpret the list of conditions for which extra rations are allowable, and the quantities of extra rations allowed, yet guard against too strict an interpretation of their policies. Liberal interpretations may be made of the principles involved, but in order that the affairs of the public

should be protected, it is further suggested that the flexibility of the program be vested in medical panels appointed to aid the state or regional rationing boards in the discharge of these particular duties.

Massachusetts, one of the first of the states to recognize the desirability of such an organization, responded with a committee appointed in June, 1943, by the president of the Massachusetts Medical Society at the request of the director of the State Office of Price Administration.

The recommendations of the subcommittee of the National Research Council, although published in October, 1943, and utilized since that time as a guide for procedure, were not accepted and put into effect by the Office of Price Administration until March 30, 1944. These recommendations, in substance, permit extra rations within qualitative and quantitative limitations for the following conditions: diabetes mellitus, active tuberculosis, chronic nephritis of the nephrotic type, cirrhosis of the liver, severe hepatitis, chronic suppurative diseases, burns, gastrointestinal lesions and pregnancy. As has been stated, these recommendations may require liberal interpretation.

Certain fundamental difficulties soon become apparent in any effort to establish a program for supplying extra rations for the sick. The need for rationed foods must obviously depend on the availability of nonrationed foods, not only as regards their actual scarcity, but also as regards their expense and their nutritional substitution value for rationed foods, due consideration being given to seasonal and geographical variations in their supply.

Since point values vary on different forms of rationed foods even inside the various groups and classes, the availability of rationed foods must also be considered in terms of local conditions of supply and demand, prices and number of ration books in a family. A person has much greater difficulty in constructing an adequate diet with one ration book, than does the marketer for a family that can pool a number of ration books in buying on a quantity basis. The frequent shifting of point values on rationed foods, depending on their nationwide availability, also creates problems that make any rigid allowances inaccurate and often inconsistent with the needs of the case.

These difficulties are implicit in the very nature of food rationing and are due largely to its elasticity—an elasticity that is vitally necessary if rationing is to be just but one requiring an equal elasticity in its modifications.

Still more fundamental are the differences in nutritional needs of various patients and in our interpretations of these needs. Regardless of disease diagnoses, the needs of no two persons are precisely alike and it is patently as absurd, except in a very general way, to try and fit with the same diet subjects of varying physical conditions and dimensions, activities, ages, sex, emotional backgrounds,

or serum was the *sine qua non* of the treatment of shock, and the large supply of plasma now available to our armed forces is the result of careful and long-sighted planning.

During the course of World War II interest has been aroused in some of the constituents of the blood other than plasma itself. MASSACHUSETTS MEDICAL SOCIETY

COMMITTEE TO AID THE DISTRICT
RATIONING OFFICER

MEDICAL RESPONSIBILITY IN FOOD RATIONING

The need for some system of food rationing made itself felt in the first year of war, when it became apparent that shortages of certain foods would give rise to inequalities of distribution and resultant hoarding, and might even cause their disappearance from the market. These shortages were due to two obvious causes—a tendency to decreased production as a result of insufficient labor and material, and an increased consumption because of the growth of the armed services and the demands of lend lease. On March 1, 1943, consequently, some months after sugar rationing had been put into effect, a point system of rationing for many meats, fats and processed foods was established.

Rationing under any circumstances is subject to difficulties: man is ever mindful of his own, and war always presents the contrasts of great sacrifices and great selfishness. In this country its difficulties are increased by the peculiarities of our national situation. We are a food-producing country, with a mixed population of diverse dietary habits. Sectional differences in food supply exist, making uniform rationing regulations inconsistent, and we have experienced, on the home front, an almost complete immunity to the perils of war.

Nevertheless, even with the relatively mild degree of food rationing to which we have so far been subjected, there was early recognized the possible need for special consideration of certain patients and institutions on account of health requirements, in order to safeguard in theory, and in practice so far as possible, the rights of all. Consequently in April, 1943, the director of the War Food Administration requested the National Research Council to appoint "a group of nationally known physicians to advise the War Food Administration concerning the extent of these special needs and the best method of meeting them."

The Subcommittee on Medical Food Requirements of the Committee on Drugs and Medical Supplies within the Division of Medical Sciences of the Council resulted. This committee studied the problem during the next few months, and published its report in the October 16 issue of the *Journal of the American Medical Association*.

The recommendations of this report form the basis on which departures from strict adherence to food rationing are made on medical grounds. They limit and interpret the list of conditions for which extra rations are allowable, and the quantities of extra rations allowed, yet guard against too strict an interpretation of their policies. Liberal interpretations may be made of the principles involved, but in order that the affairs of the public

should be protected, it is further suggested that the flexibility of the program be vested in medical panels appointed to aid the state or regional rationing boards in the discharge of these particular duties.

Massachusetts, one of the first of the states to recognize the desirability of such an organization, responded with a committee appointed in June, 1943, by the president of the Massachusetts Medical Society at the request of the director of the State Office of Price Administration.

The recommendations of the subcommittee of the National Research Council, although published in October, 1943, and utilized since that time as a guide for procedure, were not accepted and put into effect by the Office of Price Administration until March 30, 1944. These recommendations, in substance, permit extra rations within qualitative and quantitative limitations for the following conditions: diabetes mellitus, active tuberculosis, chronic nephritis of the nephrotic type, cirrhosis of the liver, severe hepatitis, chronic suppurative diseases, burns, gastrointestinal lesions and pregnancy. As has been stated, these recommendations may require liberal interpretation.

Certain fundamental difficulties soon become apparent in any effort to establish a program for supplying extra rations for the sick. The need for rationed foods must obviously depend on the availability of nonrationed foods, not only as regards their actual scarcity, but also as regards their expense and their nutritional substitution value for rationed foods, due consideration being given to seasonal and geographical variations in their supply.

Since point values vary on different forms of rationed foods even inside the various groups and classes, the availability of rationed foods must also be considered in terms of local conditions of supply and demand, prices and number of ration books in a family. A person has much greater difficulty in constructing an adequate diet with one ration book, than does the marketer for a family that can pool a number of ration books in buying on a quantity basis. The frequent shifting of point values on rationed foods, depending on their nationwide availability, also creates problems that make any rigid allowances inaccurate and often inconsistent with the needs of the case.

These difficulties are implicit in the very nature of food rationing and are due largely to its elasticity—an elasticity that is vitally necessary if rationing is to be just but one requiring an equal elasticity in its modifications.

Still more fundamental are the differences in nutritional needs of various patients and in our interpretations of these needs. Regardless of disease diagnoses, the needs of no two persons are precisely alike and it is patently as absurd, except in a very general way, to try and fit with the same diet subjects of varying physical conditions and dimensions, activities, ages, sex, emotional backgrounds,

dietary habits and racial peculiarities as it was for Procrustes to try and fit his unhappy lodgers into his single bed of fixed dimensions. Moreover, despite the prodigious advances that have been made in our knowledge of the role of diet in health and disease since Captain Cook first demonstrated the need of fresh foods on an ocean voyage, our information regarding the specific role of diet in many diseases can scarcely be considered mathematical.

With this inexactness of knowledge, there are still permissible wide variations in the views of individual physicians regarding the part that diet may play in the treatment of certain diseases, and it is frequently on the statements of these physicians that judgments must be made on the allotments requested for individual cases, in order to do justice to both the patient and the public. It must be recognized, too, that few physicians can have the information on food values and their seasonal irregularities that would be necessary for an accurate month-by-month appraisal of their patients' needs.

Strictness in the interpretation of regulations applying to extra rations must also be a variable factor, depending on the month-by-month needs of rationing. We must also bear in mind that few patients actually require more food or different food than can be obtained from their basic allotments and point-free foods, that many average-sized families do not find it necessary to use up their basic allotments, and that many active medical practitioners rarely, if ever, find it necessary to prescribe extra food allotments for their patients.

The committee appointed in this state to aid the district rationing executive had little in the way of precedent to help it in its early deliberations. After consulting authorities in various fields of medicine, however, it was decided to accept as a reasonable maximum for any diagnosis the allotments of rationed foods that had been determined as a reasonable maximum for patients with diabetes, namely, 4 pounds of processed foods and 5 pounds of meats and fats per week. These amounts include the basic rations, but do not include unrationed foods. As later developments showed, this allotment compares favorably with the diets recommended for diabetes and other diseases by the subcommittee of the National Research Council. A smaller allotment (2 pounds of processed foods and 3 pounds of meats and fats per week) was later adopted and allowed where need seemed to exist in conditions not accepted by the subcommittee of the National Research Council or where any doubt existed concerning the needs of the patient. When point values were removed from many meats these allowances were halved for meats and fats, and are continually subject to revision as conditions change.

The impossibility of attaining mathematical accuracy in the task of attempting to temper the wind

to the shorn lamb has been indicated. The best any advisory group can do is to profit by its experience, to try and keep abreast of change, improve its methods of administration in a where so little exact knowledge exists, and to rely on continuous flexibility of a program that with so many variable factors.

Figures at present available indicate that approximately 13,500 persons in Massachusetts are receiving supplemental rations, or 0.3 per cent of population. This does not seem to be an unhigh figure, but it does suggest a considerable number who have sought and failed to receive extra allotments. These requests are for a variety of conditions, some of which are patently unsuited to dietary treatment, and some of which could not reasonably be expected to be met from it according to accepted standards of treatment; they are made not infrequently for gargantuan quantities of food, the ingestion of which some patients could hardly be expected to survive.

Success in the limitation of extra allotment food to those relatively few persons who absolutely require it must depend in large measure on knowledge and integrity of practicing physicians. Admitting differences in methods of treatment in the patients treated, and taking into consideration the limitations of our knowledge, we believe nevertheless that the restrictions as established are fair ones.

It would help the committee if the physicians' statements in requesting extra food were fuller and more accurate. This would avoid long delays to the patient, occasioned by asking for further information from the doctor. For example, the committee needs more exact diagnoses; not simply "anemia," but the kind and severity; not simply "hematemesis," but the date and the existing level of hemoglobin; not simply "operation," but the date and kind. It still seems as if the number of requests for extra food was far too high and could be greatly lessened if the doctor would look at his patient more critically and ask himself if the extra ration was really a medical necessity in cases such as hemiplegia, "rheumatism," concussion, skin disease, psychoneurosis, angina, ptosis, asthenia, Parkinson's disease, irritable colon, heart disease and so forth.

The work of the advisory committee will be further expedited as information concerning rationing activities becomes more general. For months it has been found necessary to enlist its aid in the rationing problems of the other New England states except Rhode Island, due to the absence of committees in these states. It will be able to do its work more effectively when relieved of these burdens and when local committees are established, as is now planned, to work in conjunction with the rationing boards in various key cities.

AIN AND DISABILITY OF SHOULDER AND ARM DUE TO HERNIATION OF THE NUCLEUS PULPOSUS OF CERVICAL INTERVERTEBRAL DISKS*

JOST J. MICHELSEN, M.D.,† AND WILLIAM J. MIXTER, M.D.‡

BOSTON

THE clinical picture of a rupture of an intervertebral disk in the lower lumbar region has become a well-defined entity within the last few years.^{1,2} Its symptoms and signs of root compression are characteristic and easily recognized. The presence and level of the lesion can be demonstrated by lipiodol,³ which is removed after the x-ray examination.⁴ The surgical treatment of what seemed not so long ago to be "intractable sciatica" gratifying, and the number of cases successfully diagnosed and relieved is increasing steadily.

Herniation of the nucleus pulposus in the cervical region is considered to be rare. Stookey⁵ in 1927 described a group of unusual so-called "tumors" arising from the cervical intervertebral disk, and reviewed the subject thirteen years later.⁶ He distinguished three different syndromes of cervical-disk herniation: the syndrome of bilateral ventral pressure (3 cases), that of unilateral ventral pressure (3 cases) and that of nerve-root pressure (1 case). In the majority of his cases, and in those reported by Mixter and Ayer⁷ and other observers,^{8,9} the herniated cartilage produced compression of the cord. This led to the belief that the symptomatology of disk herniation in the cervical and in the lumbar region are fundamentally different. Stookey also concluded from his observations that the operative results in cervical herniations are not too encouraging.

There is evidence that cord compression as a diagnostic criterion of cervical herniation has been overemphasized. In our experience lesions of cervical disks produced compression of the cord in 6 cases, and involvement of nerve roots was the predominant feature in 8 cases. Stookey described the picture of root compression as consisting of muscle atrophy and hypotonia, limited to the dis-

tribution of the roots involved and producing purely subjective sensory symptoms, such as burning, gnawing and tingling, which may be increased by movement of the extremity.

Spurling's¹⁰ patient complained of severe pain in the lower neck and tip of the shoulder and pain and inability to abduct the left arm. The onset of the disability was preceded by a "strain of the neck." The pain was exacerbated by sneezing, coughing and straining. On the first admission tenderness of the fifth and sixth cervical spinous processes and hypesthesia in approximately the fifth cervical dermatome over the tip of the shoulder were found. Nine years later there was atrophy of the left deltoid and infraspinatus muscles and inability to abduct the left arm, in addition to the sensory changes previously observed. The total protein in the cerebrospinal fluid was 80 mg. per 100 cc. A doubtful filling defect on the left between the sixth and seventh cervical vertebrae was seen on lipiodol examination. Laminectomy revealed a mass compressing the sixth cervical nerve root against the overlying ligamentum flavum. It was not removed because "direct attack on the protrusion would have led to damage to the nerve and possibly the spinal cord." The decompression gave relief of symptoms.

Hanflick¹¹ described a case with a herniated nucleus pulposus at the sixth cervical interspace. The patient complained of pain, aggravated by coughing, sneezing and straining, in the left side of the neck, left costocoracoid area, left arm, left forearm and second and third fingers, with paresthesias of these two fingers — hyperesthesia to pinprick and hypesthesia to touch and vibration. The total protein in the cerebrospinal fluid was 83 mg. per 100 cc. Fluoroscopy after lipiodol injection disclosed an extramedullary lesion between the sixth and seventh cervical vertebrae. Laminectomy and removal of the disk fragment gave complete relief of symptoms. Head traction had previously been used without effect.

dietary habits and racial peculiarities as it was for Procrustes to try and fit his unhappy lodgers into his single bed of fixed dimensions. Moreover, despite the prodigious advances that have been made in our knowledge of the role of diet in health and disease since Captain Cook first demonstrated the need of fresh foods on an ocean voyage, our information regarding the specific role of diet in many diseases can scarcely be considered mathematical.

With this inexactness of knowledge, there are still permissible wide variations in the views of individual physicians regarding the part that diet may play in the treatment of certain diseases, and it is frequently on the statements of these physicians that judgments must be made on the allotments requested for individual cases, in order to do justice to both the patient and the public. It must be recognized, too, that few physicians can have the information on food values and their seasonal irregularities that would be necessary for an accurate month-by-month appraisal of their patients' needs.

Strictness in the interpretation of regulations applying to extra rations must also be a variable factor, depending on the month-by-month needs of rationing. We must also bear in mind that few patients actually require more food or different food than can be obtained from their basic allotments and point-free foods, that many average-sized families do not find it necessary to use up their basic allotments, and that many active medical practitioners rarely, if ever, find it necessary to prescribe extra food allotments for their patients.

The committee appointed in this state to aid the district rationing executive had little in the way of precedent to help it in its early deliberations. After consulting authorities in various fields of medicine, however, it was decided to accept as a reasonable maximum for any diagnosis the allotments of rationed foods that had been determined as a reasonable maximum for patients with diabetes, namely, 4 pounds of processed foods and 5 pounds of meats and fats per week. These amounts include the basic rations, but do not include unrationed foods. As later developments showed, this allotment compares favorably with the diets recommended for diabetes and other diseases by the subcommittee of the National Research Council. A smaller allotment (2 pounds of processed foods and 3 pounds of meats and fats per week) was later adopted and allowed where need seemed to exist in conditions not accepted by the subcommittee of the National Research Council or where any doubt existed concerning the needs of the patient. When point values were removed from many meats these allowances were halved for meats and fats, and are continually subject to revision as conditions change.

The impossibility of attaining mathematical accuracy in the task of attempting to temper the wind

to the shorn lamb has been indicated. The best that any advisory group can do is to profit by its own experience, to try and keep abreast of changes and improve its methods of administration in a field where so little exact knowledge exists, and to insist on continuous flexibility of a program that deals with so many variable factors.

Figures at present available indicate that approximately 13,500 persons in Massachusetts are receiving supplemental rations, or 0.3 per cent of the population. This does not seem to be an unduly high figure, but it does suggest a considerably greater number who have sought and failed to receive extra allotments. These requests are made for a variety of conditions, some of which are patently unsuited to dietary treatment, and others of which could not reasonably be expected to benefit from it according to accepted standards of treatment; they are made not infrequently for gargantuan quantities of food, the ingestion of which some patients could hardly be expected to survive.

Success in the limitation of extra allotments of food to those relatively few persons who absolutely require it must depend in large measure on the knowledge and integrity of practicing physicians. Admitting differences in methods of treatment and in the patients treated, and taking into consideration the limitations of our knowledge, we believe nevertheless that the restrictions as established are fair ones.

It would help the committee if the physicians' statements in requesting extra food were fuller and more accurate. This would avoid long delays for the patient, occasioned by asking for further information from the doctor. For example, the committee needs more exact diagnoses: not simply "anemia" but the kind and severity; not simply "hematemesis," but the date and the existing level of the hemoglobin; not simply "operation," but the date and kind. It still seems as if the number of requests for extra food was far too high and could be greatly lessened if the doctor would look at his patient more critically and ask himself if the extra ration is really a medical necessity in cases such as hemiplegia, "rheumatism," concussion, skin disease, psychoneurosis, angina, ptosis, asthenia, Parkinson's disease, irritable colon, heart disease and so forth.

The work of the advisory committee will be further expedited as information concerning its activities becomes more general. For months it has been found necessary to enlist its aid in the rationing problems of the other New England states except Rhode Island, due to the absence of committees in these states. It will be able to do its work more effectively when relieved of these burdens, and when local committees are established, as is now planned, to work in conjunction with the rationing boards in various key cities.

PAIN AND DISABILITY OF SHOULDER AND ARM DUE TO HERNIATION OF THE NUCLEUS PULPOSUS OF CERVICAL INTERVERTEBRAL DISKS*

JOST J. MICHELSEN, M.D.,† AND WILLIAM J. MIXTER, M.D.‡

BOSTON

THE clinical picture of a rupture of an intervertebral disk in the lower lumbar region has become a well-defined entity within the last few years.^{1,2} Its symptoms and signs of root compression are characteristic and easily recognized. The presence and level of the lesion can be demonstrated by lipiodol,³ which is removed after the x-ray examination.⁴ The surgical treatment of what seemed not so long ago to be "intractable sciatica" is gratifying, and the number of cases successfully diagnosed and relieved is increasing steadily.

Herniation of the nucleus pulposus in the cervical region is considered to be rare. Stookey⁵ in 1927 described a group of unusual so-called "tumors" arising from the cervical intervertebral disk, and reviewed the subject thirteen years later.⁶ He distinguished three different syndromes of cervical-disk herniation: the syndrome of bilateral ventral pressure (3 cases), that of unilateral ventral pressure (3 cases) and that of nerve-root pressure (1 case). In the majority of his cases, and in those reported by Mixter and Ayer⁷ and other observers,^{8,9} the herniated cartilage produced compression of the cord. This led to the belief that the symptomatology of disk herniation in the cervical and in the lumbar region are fundamentally different. Stookey also concluded from his observations that the operative results in cervical herniations are not too encouraging.

There is evidence that cord compression as a diagnostic criterion of cervical herniation has been overemphasized. In our experience lesions of cervical disks produced compression of the cord in 6 cases, and involvement of nerve roots was the predominant feature in 8 cases. Stookey described the picture of root compression as consisting of muscle atrophy and hypotonia, limited to the dis-

tribution of the roots involved and producing purely subjective sensory symptoms, such as burning, gnawing and tingling, which may be increased by movement of the extremity.

Spurling's¹⁰ patient complained of severe pain in the lower neck and tip of the shoulder and pain and inability to abduct the left arm. The onset of the disability was preceded by a "strain of the neck." The pain was exacerbated by sneezing, coughing and straining. On the first admission tenderness of the fifth and sixth cervical spinous processes and hypesthesia in approximately the fifth cervical dermatome over the tip of the shoulder were found. Nine years later there was atrophy of the left deltoid and infraspinatus muscles and inability to abduct the left arm, in addition to the sensory changes previously observed. The total protein in the cerebrospinal fluid was 80 mg. per 100 cc. A doubtful filling defect on the left between the sixth and seventh cervical vertebrae was seen on lipiodol examination. Laminectomy revealed a mass compressing the sixth cervical nerve root against the overlying ligamentum flavum. It was not removed because "direct attack on the protrusion would have led to damage to the nerve and possibly the spinal cord." The decompression gave relief of symptoms.

Hanflig¹¹ described a case with a herniated nucleus pulposus at the sixth cervical interspace. The patient complained of pain, aggravated by coughing, sneezing and straining, in the left side of the neck, left costocoracoid area, left arm, left forearm and second and third fingers, with paresthesias of these two fingers — hyperesthesia to pinprick and hypesthesia to touch and vibration. The total protein in the cerebrospinal fluid was 83 mg. per 100 cc. Fluoroscopy after lipiodol injection disclosed an extramedullary lesion between the sixth and seventh cervical vertebrae. Laminectomy and removal of the disk fragment gave complete relief of symptoms. Head traction had previously been used without effect.

Semmes and Murphey¹² observed a group of 4 cases with apparent unilateral rupture of the sixth cervical disk, in 3 of which this diagnosis was proved at operation. They proposed a syndrome characterized by pain in the neck, shoulder, precordium and arm and by sensory changes in the index and middle fingers. The pain was made worse by sneezing, coughing and straining and by movements of the neck. The important findings on examination included tenderness over the exit of the seventh cervical nerve root from the spinal canal and over the scapula, hypesthesia in the index finger, slight reduction of sensibility of the middle finger, normal arm and leg reflexes and absent cervical lordosis on the x-ray films. The total protein was increased in 2 cases. No lipiodol examinations were performed. The site of the lesion was localized during the operation, which was carried out under local anesthesia. Gentle pressure on the ligamentum flavum reproduced the pain, and novocain infiltration of the corresponding nerve root abolished it. Two of these patients were completely relieved.

The present report is based on experiences with 8 cases, all of which were proved pathologically at operation. There were lesions at the fifth cervical interspace in 4 cases, at the sixth in 3, and at the seventh in 1, with encroachment on the sixth, seventh and eighth cervical nerve roots, respectively.

CASE REPORTS

CASE 1 (M. G. H. 334269). A. T. S., a 45-year-old unemployed weaver, was admitted to the Massachusetts General Hospital for the second time in April 23, 1934, because of pain and weakness of left shoulder and arm. Twenty-two months prior to admission, a crank he was turning to raise the body of a dump car slipped and struck his left arm just below the deltoid muscle. There was local pain for several days. Eleven months later pain and numbness began in the anterolateral left upper arm, antecubital region and forearm; it was made worse by movements of the arm, which became weaker and smaller.

Examination revealed atrophy of the left upper arm, particularly of the deltoid and biceps. There were muscle twitchings of the deltoid. The arm reflexes were apparently equal, the left knee jerk was more active than the right, and the left plantar response was equivocal. There was hyperesthesia to pinprick and temperature in the antecubital region and a small area above the spine of the scapula. A lumbar puncture showed a protein level of 43 mg. per 100 cc. The cisternal fluid contained 24 mg. The dynamics were equivocal. A lipiodol examination was unsuccessful because the lipiodol could not be moved from the cistern.

At operation a hard, fibrous mass of tissue 1.0 cm. in diameter and 0.2 cm. in thickness was found between the 5th and 6th cervical vertebrae impinging on the cord. Because of brisk bleeding it was not removed. On later check-up examination the patient was found to have weakness of the biceps and deltoid but was able to do odd jobs.

CASE 2. (M. G. H. 27277). O. A., a 49-year-old automobile-body worker, was admitted to the hospital on March 4, 1937, complaining of pain in the right shoulder and arm. He had been entirely well until 5½ months previously, when he fell, striking the back of his neck and right shoulder on a projection. He had pain in that region for 30 minutes and then resumed his work. One week later, he began to have pain in the posterior right side of the neck, right shoulder

and upper arm and a sensation of numbness in the upper arm made worse by coughing, sneezing, straining and motion and not relieved by medication, physiotherapy or strapping. A Thomas collar improved the pain, except on sneezing and coughing, for 8 weeks, when the symptoms progressed. Pain in the back of the neck, shoulder and arm became severe. Flexion, extension and lateral flexion of the neck caused numbness involving the whole arm and hand, particularly the thumb and index finger. The arm became weak and then were tremors of the muscles of the upper arm.

Examination revealed tenderness to the right of the 5th cervical vertebra and the spine of the scapula, the latter being accompanied by numbness in the arm. There was some weakness of the right arm and hypesthesia over the radial side of the forearm and the deltoid region. The reflexes of the right arm were diminished and the right ankle jerk was more active than the left. There were no pathologic reflexes. The cerebrospinal-fluid protein was 60 mg. per 100 cc. at the lumbar level and 17 mg. at the cisternal. Lipiodol examination revealed a partial block at the upper margin of the 6th cervical body. On laminectomy the 6th cervical root was found to be compressed by a ruptured disk fragment, which was removed. The patient was improved when discharged. On check-up examination and by correspondence later it was found that the patient continued to have some soreness of the right upper arm and forearm.

CASE 3 (M. G. H. 181151). J. F. B., a 38-year-old butcher, was admitted to the hospital on March 30, 1939, for pain and paresthesias in the left shoulder and arm. Five years previously he was struck by an automobile, and he grasped the radiator cap to ride the car with his knees on the bumper. There was stiffness of the neck for 4 to 5 weeks, diagnosed as strain of the cords of the left neck and shoulder. Five months previously he noticed a sensation of "pins and needles" in the left arm when he was tipped back in a barber's chair, the sensation persisting until the headrest was raised. Since then this sensation had been felt more frequently, particularly in tilting the head to the left and lying on the left shoulder. Two months later the patient began to suffer from constant tearing pain in the anterolateral region of the left upper arm and scapula. The paresthesias became almost constant, involving the radial forearm, thumb and index finger. The discomfort was aggravated by tilting the head to either side, use of the left arm and lying on the left shoulder. Some relief was obtained by raising the left arm over the head.

On examination all movements of the head against resistance and to the left without resistance produced pain over the scapula and anterolateral upper arm and paresthesias in the left radial forearm, thumb and index finger. There was some hyperalgesia over the left shoulder blade and antecubital space and hypesthesia of the left thumb. The left radial and biceps reflexes were less active than those on the right. Other reflexes were normal, and there were no pathologic reflexes. X-ray examination showed absence of cervical lordosis. Lipiodol examination was suggestive of delay in the transport of the lipiodol between the 5th and 6th cervical vertebrae on the left side. The total protein of the cerebrospinal fluid was 47 mg. per 100 cc. at the lumbar level and 25 mg. at the cisternal.

Laminectomy revealed a ruptured disk fragment compressing the 6th cervical nerve root, which was removed. The patient was symptom free after recovery from the operation, and remained so at a check-up examination two months later, at which time he was ready to go back to work.

CASE 4 (M. G. H. 397940). L. A. T., a 53-year-old farmer, entered the hospital on March 25, 1943, with complaints of pain in the neck, left shoulder and arm. Twenty years previously he fell 12 feet from a barn roof, hitting the ground with his feet down and suffering a fracture of the right knee. Six weeks before admission he slipped on the ice, wrenching his left shoulder. The pain in the left arm began 6 years previously, at first occurring only during the night. It involved the antecubital region and was associated with numbness. After the second accident both the pain and the numbness became more continuous and widespread, including the lower midcervical region and left shoulder blade and radiating over the collarbone into the deltoid region and the radial forearm. The pain, which was described as "like electricity" and "like a toothache," was made worse

turning the head to the right and by flexing it. Traction made it worse.

At examination the head was seen to be tilted to the right. Cervical spine was held rigid and was tender to pressure in its lower part. There was marked atrophy of the left biceps muscle. Motions of the left arm and hand were weak. All joints. There was hypesthesia of the lateral aspect of upper arm and the radial aspect of the forearm. The biceps, radial and abdominal reflexes were less active than those on the right. Both triceps reflexes were absent. Left knee and ankle jerks were more active than those on right, and there was a Babinski sign on the left. X-ray examination of the cervical spine revealed absence of cervical lordosis and slight tilting of the head to the right. The side of the diaphragm was elevated. Lipiodol examination showed a suggestive defect at the level of the 5th cervical interspace. The total protein of the lumbar cerebrospinal fluid was 75 mg. per 100 cc.

At operation a disk fragment compressing the left 6th cervical nerve root was found and removed. Recovery was prompt and relief was complete. The patient returned to his old job and subsequently reported, "My health is the best it has been for many years."

CASE 5 (M. G. H. 296875). J. H. O., a 43-year-old engineer, was brought to the hospital on April 8, 1941, because of weakness of both legs and arms. Twenty-three years previously he had a fall while on cavalry drill in France. Three years later he began to have "stiff necks" and pain in the left shoulder and arm, intermittently. Later on, these attacks occurred more frequently. Three weeks prior to admission he noticed a steady, sharp pain over the left shoulder blade, dorsolateral upper arm and dorsal forearm. Paresthesias in the index and middle fingers, which were aggravated by moving the spine. Because of this pain he had been unable to lie in bed for the past week. A physician recommended extraction of three teeth. When the third molar was pulled, the patient's whole body stiffened. Severe shooting pain in both hands and both feet was noted and the old shoulder and arm pain disappeared. When he tried to get out of his car at home he was unable to move his hands and feet, which felt numb. During the next few days the strength in the arms and right leg partially returned, but he was unable to pass his urine and was incontinent of feces.

Examination revealed a marked weakness of the left leg, weakness of the right leg and weakness of the grip of both hands, more so on the left side. There was anesthesia, pinprick and temperature over the right side of the body, with its upper level at the clavicle and the inner side of the right arm. There was hypesthesia to pinprick and temperature over the left chest, the left inner arm and the dorsolateral aspect of the upper arm and forearm. The arm and leg reflexes were brisk and more active on the left side than on the right. There were unsustained knee and ankle clonus, and the plantar reflexes were equivocal and possibly extensor on the left side. The bladder was paralyzed. Compression of the jugular veins produced increased numbness. A lumbar puncture showed a complete block and a total protein of 67 mg. per 100 cc. X-ray examination of the cervical spine revealed narrowing of the 5th and 6th cervical interspaces and extensive spur formation in the anterior margins of the 5th, 6th and 7th cervical vertebrae.

At operation a disk fragment was found compressing the 6th cervical root on the left side and was removed. Following the operation the patient had a complete paralysis of both legs, which gradually subsided with return of bladder and bowel function. He is able to walk and use his arms and does odd jobs, but there is still a marked pyramidal deficit.

CASE 6 (M. G. H. 392078). V. T., a 32-year-old floorman, was admitted to the hospital on February 12, 1943, for pain in the right scapular region and right arm. Sixteen years previously he had a fall, landing on his neck. There was weakness in both arms and numbness and tenderness over the anterior chest below the clavicles for 2 or 3 months. Nine years previously he suffered a concussion while playing football, with loss of consciousness for 1 or 2 hours. Two years later he noticed pain in the right scapular region, which was not affected by motions of the neck and was relieved by the extraction of teeth.

Six months prior to admission, the patient noticed pain over the upper part of the right scapula, particularly on bending the neck forward and backward. Two months later the back pain was accompanied by shooting pain in the right side of the chest, the anterolateral aspect of the upper arm, the antecubital region and the radial forearm. This pain was aggravated by sneezing and coughing. It could be relieved by extending the arm over the head. There was also a constant ache in the upper arm and forearm and tingling of the fingertips. Traction and medication were of no effect. The right arm became gradually weaker, pushing motions being chiefly affected. There were also twitchings of the biceps muscle and trembling of the hand.

Examination revealed atrophy of the right triceps and deltoid muscles, weakness on abduction at the shoulder and on extension of the forearm and fasciculations of the deltoid muscle. There were no distinct sensory disturbances. The right triceps reflex was less active than the left. Other reflexes were normal. X-ray examination of the cervical spine showed narrowing of the 6th cervical interspace. The total protein of the lumbar cerebrospinal fluid was 67 mg. per 100 cc. Lipiodol examination showed delay of transport opposite the 6th cervical interspace on the right.

At operation a disk fragment was found compressing the right 7th cervical root and was removed. The pain was instantly relieved and convalescence was uneventful. The strength and size of the affected muscles gradually became normal. The patient returned to work 3 months after the operation. At a recent check-up examination he stated, "I am lifting 20 tons of clothes each day."

CASE 7 (M. G. H. 407258). E. F., a 43-year-old mill hand, was admitted to the hospital on June 17, 1943, because of pain in the left shoulder and left arm. Six months previously while wrestling he fell against a parked car, striking his eye; three stitches were taken in the eyelid. Five weeks prior to admission he began to have severe stabbing pain involving the left shoulder blade, the dorsolateral aspect of the left upper arm and the dorsolateral aspect of the forearm on bending the head backward or turning it to the left side. The pain was associated with a tingling sensation in the dorsolateral forearm and index finger. The pain and numbness gradually became more severe and almost constant. Twitchings of the biceps muscle were also noted.

Examination showed atrophy of the left upper arm and muscle-bundle twitchings of the biceps muscle. There was marked weakness of the triceps muscles, mild weakness of the biceps muscles and some weakness of the other muscles of the forearm and hand. Hypesthesia was found over the dorsolateral aspect of the upper arm and forearm. The triceps reflex was diminished; other deep and superficial reflexes were normal. X-ray examination of the cervical spine revealed absent cervical lordosis and narrowing of the 6th cervical interspace. Lipiodol examination suggested an obstruction to the flow at a point opposite the left side of the 6th cervical interspace. The total protein of the cerebrospinal fluid was 48 mg. per 100 cc. at the lumbar level and 28 mg. at the cisternal. At operation a disk fragment was found compressing the left 7th cervical root and was removed. The postoperative course was uneventful. The patient was entirely relieved, returning to his job 4 weeks after the operation and continuing regularly since then.

CASE 8 (M. G. H. 221689). C. H. M., a 68-year-old physician, entered the hospital on November 10, 1939, with complaints of pain involving the left scapula, the ulnar side of the left arm and the little finger. Three weeks previously, while pitching horseshoes, he twisted his back and felt deep underneath the left scapula a sudden, sharp pain that radiated across the axilla down the inner upper arm, elbow and forearm into the little finger. The pain was intermittent at first, but became more constant and dull. There also was numbness in the little finger. The pain was relieved by abduction and external rotation of the upper arm with internal rotation of the forearm — by grasping the head of the bed or resting the hand under the head. The pain was increased by extension of the head.

Positive findings included tenderness of the 7th cervical spinous process, with radiation of pain down the inner arm to the little finger. The pain was reproduced by hyperextension of the head and deep pressure in the left supraclavicular

area. Extension of the forearm, adduction of the thumb, flexion of the little finger and adduction and abduction of all the fingers were slightly weak. The little finger and inner arm were a little less sensitive to pain, temperature, touch and vibration than normal. The reflexes were equal and normal with the exception of the left triceps reflex, which was extremely sluggish. No pathologic reflexes were found. X-ray examination showed mild hypertrophic changes about the margins of the lower cervical and dorsal vertebrae and diffuse osteoporosis. Lipiodol examination was inadequate owing to the patient's condition. The total protein in the lumbar spinal fluid was 103 mg per 100 cc and that in the cisternal 49 mg. Head traction was tried but was not tolerated.

At operation the left 8th cervical root was found to be compressed by a disk fragment, which was removed. Convalescence was uneventful and the pain disappeared. The patient was able to resume practice three months after the operation.

THE ROOT-COMPRESSION SYNDROME

In spite of the difference in level these cases had certain features in common. These will be analyzed

that movements such as turning and tilting the head and forward and backward bending of the neck made their discomfort worse. Other exacerbating factors were motions of the involved arm except for combined abduction and external rotation of the upper arm and internal rotation of the forearm, which were used by 3 patients to relieve the pain. Sneezing and coughing as aggravating factors were recorded in 3 cases.

Four patients complained of weakness of the arm, and 3 of them observed twitchings of some of the arm muscles.

The duration of the symptoms varied from three weeks to twenty-two years. In 4 patients it was from five to seven months.

In only 1 case did the onset of the characteristic disturbances occur at the time of the trauma. In the other patients the symptoms immediately follow-

TABLE 1. *Nature of Injury and General Symptomatology*

CASE NO.	AGE	SEX	TIME	INJURY	NATURE	IMMEDIATE SYMPTOMS	DURATION	LATE SYMPTOMS	
								NATURE	
1	37								
44		M	22 mo ago	Crank struck left arm		Pain in deltoid region for several days	11 mo	Pain, paresthesias and weakness in left arm and shoulder	
2	49	M	5½ mo ago	Struck back of neck and right shoulder on projection		Pain in right deltoid region for ½ hr	5 mo	Pain, paresthesias and weakness in right arm and shoulder, twitchings	
3	38	M	5 yr ago	Struck by car		Stiffness in neck and left shoulder for 4 to 5 wk	5 mo	Pain and paresthesias in left arm and shoulder	
4	53	M	20 yr ago	Fell 12 feet, landing with right foot on a boulder		Fracture of right knee — exacerbation of shoulder and arm pain	5 to 6 yr	Pain and paresthesias in left shoulder and arm	
			6 wk ago	Slipped on ice, wrenched left shoulder					
5	43	M	23 yr ago	Fell off horse		Apparently no ill effects	22 yr	Intermittently stiff neck, pain and paresthesias in left shoulder and arm, recently sudden paraplegia	
			3 wk ago	Forceful manipulation of neck		Paraplegia			
6	32	M	17 yr ago	Fell on neck		Arms "paralyzed" for 3 wk, numbness and tenderness over chest	6 mo	Pain, paresthesias and weakness in right arm and shoulder, twitchings	
7	43	M	6 mo ago	Fell against car while wrestling		Laceration above eye, headaches	6 wk	Pain and paresthesias in left shoulder and arm, twitchings	
8	68	M	3 wk ago	Twisted back pitching horseshoes		See case record	3 wk	Pain, paresthesias and weakness in left shoulder and arm	

first, after which the syndromes characteristic of each level will be discussed.

All the 8 patients at some time prior to the onset of their recent illness received an injury. The different types of injury, the age and sex of the patients at the time of admission, the onset and the type of symptoms are summarized in Table 1.

The ages varied from thirty-two to sixty-eight years, with an average age of forty-six years. All the patients were men. In 6 cases the left side was involved.

The symptoms that brought the patients to the hospital were pain associated with paresthesias in the region of the scapula, arm and hand. The pain was usually described as stabbing, shooting, sharp or acute. Only 3 patients complained also of pain in the lower part of the neck. In 3 others there was no history of discomfort referable to the neck. Two patients noticed pain and paresthesias in the scapular region and arm for the first time on certain movements of the neck. All patients except 1, however, stated

ing the injury were different from those experienced weeks, months or many years later. It should be mentioned, however, that the patient in Case 3 had a stiff neck for four or five weeks following the injury. It was diagnosed as strain of the cords of the left neck and shoulders. In Case 6 there was motor paralysis of both arms and paresthesias for three weeks after the patient's fall. In Case 4 the patient, who suffered two accidents, noticed an exacerbation of the symptoms after the second one.

During the course of the recent illness in any given case the type of symptoms remained about the same, but the intensity of the sensory manifestations increased and weakness, if present, became more pronounced. Only in 1 case (Case 5) did the type of symptoms change entirely, the patient becoming paralyzed during a dental operation. He was included in this series because for twenty-two years he had suffered from intermittent spells of stiffness of the neck and shooting pains in

the left shoulder and upper arm much like those experienced by the other patients.

The motor and sensory findings are summarized in Table 2. On the involved side weakness of certain muscles and diminution of arm reflexes were observed in 7 cases and atrophy and fasciculations in 4. Marked involvement of the pyramidal tracts as present in Case 5. In 3 other patients mild

changes of the lower cervical spine in 4 and absent cervical lordosis in 4. Narrowing of an interspace was always associated with hypertrophic changes. In 2 cases there was a combination of narrowing, hypertrophic changes and absent lordosis.

The different distribution of the sensory manifestations resulting from root compression at the fifth, sixth and seventh interspaces is shown in

TABLE 2. Motor and Sensory Disturbances.

CASE No	SIDE OF LESION	MOTOR DISTURBANCES					LEGS	SENSORY DISTURBANCES	
		ARM (ON SIDE OF LESION)						ARM (ON SIDE OF LESION)	OTHER PARTS OF BODY
		Atrophy	Weakness	Fibrillations	Reflexes	Weakness	Reflexes		
1	Left	Yes	Yes	Yes	Normal(?)	No	Left knee jerk more active, left plantar indefinite	Yes	No
2	Right	No	Yes	Yes	Diminished	No	Right ankle jerk more active	Yes	Possibly right side of neck and chest
3	Left	No	No	No	Diminished	No	Normal	Yes	No

in which there was a Brown-Séquard syndrome, and Case 2, in which the disturbance was indefinite.

Tenderness of the lower cervical spine was demonstrated in 3 cases, of the scapula in 2, and of the arm muscles in 2 cases.

The examination of the lumbar cerebrospinal fluid revealed an elevated protein in 5 patients and high borderline values in the others. In only 1 case was the cisternal fluid abnormal. The dynamics were not affected except in Case 5, which had a complete block.

X-ray examination of the cervical spine showed narrowing of an interspace in 3 cases, hypertrophic

middle fingers were affected by compression of the seventh cervical root at the sixth interspace. The lesion at the seventh interspace (eighth cervical root) produced sensory abnormalities of the scapula, the inner side of the upper arm and forearm and the little finger.

There was obvious motor dysfunction of the biceps and deltoid muscles in 2 cases with compression of the sixth cervical root, and of the deltoid, biceps and triceps muscles in 2 cases with involvement of the seventh nerve root. Implication of the eighth nerve root seemed to be associated with weakness of the triceps, adductor of the thumb,

flexor of the little finger and interossei muscles.

The narrowing of the sixth interspace shown on the x-ray plates was at the sixth interspace in all 3 cases with the lesion at this level.

Lipiodol examination was done in 7 cases, with suggestive results in 4 of them.

COMMENT

The data just presented indicate that pain and disability of the shoulder and arm were the prominent symptoms in this group of patients.

The character of the pain and its association with paresthesias suggested that it was due to involvement of the nervous system. It was exacerbated by flexion, hyperextension and tilting of the neck and certain movements of the arm, and also by sneezing and coughing. It did not follow the course of any particular peripheral nerve. These features and the demonstration of the underlying pathology make it certain that the pain resulted from disease involving the sensory roots. One also may infer that the areas in which this pain and the other sensory abnormalities occurred represented the dermatomes supplied by the affected posterior roots.

With herniations at the fifth interspace, the scapula and the anterolateral aspect of the upper arm were involved in all 4 cases and the antecubital region and radial forearm in 3 cases. The site on the forearm in 1 case was not recorded. The thumb and index finger were affected in 2 cases. Figure 1 shows that this pattern follows fairly closely the arrangement of the sixth cervical dermatome as outlined by Foerster,¹³ with the exception of the radial forearm. On the chart by Pauchet and Dupret¹⁴ the sixth cervical dermatome is represented on the radial forearm.

In the second group with herniations at the sixth interspace, the scapula, dorsolateral upper arm and dorsal forearm were implicated in all cases, the index and middle fingers, and the index finger alone in 1 case each, and the fingertips in the third case. The scapular pain, which was definite, could not be explained by using Foerster's outline. In Pauchet and Dupret's outline the seventh cervical dermatome is represented in this area. In both figures the seventh cervical dermatome does not include the dorsolateral aspect of the upper arm.

The only patient in this group who had a herniation at the seventh interspace presented sensory manifestations in accordance with the outline of Pauchet and Dupret, including the shoulder blade, the inner, upper and lower arm and the little finger.

The distribution of the sensory phenomena in the upper arm and forearm and shoulder appeared to be consistent and characteristic for each root. The pattern of the sensory manifestations of the fingers was not uniform. In 2 cases with involvement of the sixth cervical root the fingers remained free. The index finger, which Semmes and Murphey¹² believe is almost entirely innervated by the seventh

cervical root, and the thumb were affected in the other 2 cases. Compression of the seventh cervical root produced manifestations in the index finger, both in the index and middle finger, and on the fingertips. These differences were probably due to variations of the dermatome distribution, which are known to occur particularly in the fingers.^{12, 14}

The question may also be raised whether involvement of the scapula, observed in all the patients

FIGURE 1. Distribution of Cervical Dermatomes. The upper drawings (A) are according to Foerster,¹³ and the lower (B) according to Pauchet and Dupret.¹⁴

regardless of the level, is due to an overlap phenomenon or a true representation of the affected roots in this area. Study of a larger number of cervical-disk cases will be necessary for a better understanding of all these problems, and perhaps of the extent of cervical dermatomes in general. The different outlines found in the textbooks are extremely confusing.

Semmes and Murphey did not describe the distribution of the arm pain in their patients with herniation of the sixth interspace. Their findings with reference to the index and middle fingers and

shoulder are in agreement with ours. The question of heart disease as the underlying pathology did not come up in these cases. Only 1 patient experienced pain over the chest, but he had a right-sided lesion. The absence of neck pain in 5 of 8 patients is worth emphasizing.

As to the motor dysfunction, diminution of reflexes of the involved arm were usually present without significant difference of the biceps, triceps, and radial reflexes at different levels of the herniation.

Weakness, atrophy and twitchings of the biceps and deltoid muscles were recorded in lesions at the fifth interspace, of the deltoid, biceps and triceps muscles at the sixth, and of the triceps, adductor pollicis, flexor digiti quinti and interossei muscles at the seventh. The records, however, were not too clear with reference to the analysis of the motor disability, perhaps because pain interfered with a systematic examination. A more detailed examination and the use of chronaxie determinations and electromyograms in the future may be of some value for a better definition of the motor changes. The number of the muscles affected by involvement of the respective anterior roots should be greater than have been observed if the present knowledge of the motor segmental innervation is correct.

With the exception of Case 5, which can be omitted from the discussion, symptoms of the long tracts of the spinal cord were absent. The dynamics of the cerebrospinal fluid were normal, and although mild or equivocal pyramidal signs were recorded in 4 cases, the basic clinical picture in all 7 cases was not due to cord compression.

X-ray changes of diagnostic value comprised absent cervical lordosis and narrowing of the sixth cervical interspace. The latter was found in all 3 cases with herniation at this level. Semmes and Murphey found loss of the cervical curve in 2 cases but no narrowing of the disk. The cerebrospinal fluid examination was useful when the total protein was elevated. In 2 of the cases with a doubtful value, x-ray changes and other evidence led to a lipiodol examination, which suggested the presence of the lesion.

The lipiodol findings were negative in only 1 case; in 2 cases it could not be moved from the site of the injection, and in 4 cases there was a delay of the passage of the oil at the level of the protruded disk. In the more recent cases the oil was removed after the examination at the lumbar level, as suggested by Kubik and Hampton.⁴

DIFFERENTIAL DIAGNOSIS

When a patient presents himself with ordinary complaints of pain in the shoulder and arm, the discovery of the true seat of the disease may be beset with difficulties. Arthritis of the spine and shoulder, bursitis, brachial neuralgia and neuritis, cervical rib, elongated transverse processes of the

seventh cervical vertebra and more recently scalenus anticus syndrome are popular diagnoses. Semmes and Murphey¹² emphasized the similarity of their syndromes and coronary disease. One might as well also include gall-bladder disease if the herniation is on the right side, pleurisy and tumors of the apex of the lung. Some of these syndromes are vaguely defined clinically as well as pathologically and their separation from each other is not always possible. The addition of a new entity to this long list seems to complicate things even more, but actually it may simplify the problem. Undoubtedly a fair number of cases formerly treated under one of the customary diagnoses will be interpreted and handled more rationally if the picture of cervical-root compression by a disk fragment becomes better known.

It is beyond the scope of this paper to discuss seemingly similar symptoms and signs of the aforementioned entities and the syndrome of a ruptured disk. Usually a good history with careful evaluation of the complaints shows the specific nature of the symptoms. As pointed out before, root pain has certain characteristics. If it is not recognized as such by its quality and distribution, its onset and course and the factors that aggravate or relieve it may be suggestive. Acromial bursitis, for instance, interferes with the abduction and outward rotation of the upper arm, which is very painful. Several of these patients volunteered the information that this particular movement relieved their pain. The mechanical irritation by a cervical rib or tight scalenus anticus muscle is lessened by tilting the head to the affected side; the reverse was true in these cases.

Regardless of whether the complaints of the patient can be properly evaluated, a systematic neurologic examination, including lumbar puncture and possibly lipiodol studies, is indicated, if other measures fail to disclose some definite underlying lesion. Occasionally a lumbar puncture alone or the combination of an absent cervical lordosis and narrowing of an interspace decides the issue, but it is not one symptom or sign that characterizes a clinical entity. A satisfactory diagnosis is based on collateral evidence.

Table 4 shows the more important findings in 7 cases.* Every one of these patients showed a combination of signs that is not compatible with extraspinal disease. The syndrome was that of intraspinal disease, unlike that of a tumor or syringomyelia, not to mention other less relevant possibilities.

TREATMENT

All patients had various forms of treatment prior to their hospital admission, without permanent relief. Such measures comprised baking and massage,

*Case 5 was omitted because of obvious cord compression on admission.

lamp treatments, strapping and head traction. One patient was injected locally with novocain. The laminectomy and removal of the disk fragment produced good results in 6 cases. In 1 case the improvement was not too impressive. In one of the early cases in which the disk fragment could

In the recent cases the operation consisted of subtotal hemilaminectomy. Small pieces of bone were removed from the adjacent lamina on one side. A lateral opening in the dura was made and only the nerve roots were exposed. After gentle retraction of the roots the disk was removed transdurally.

not be removed for technical reasons, the pain was relieved but the motor disability persisted. In Case 5, with recent cord compression, gradual improvement of the motor and sensory functions of the long

Figure 2 shows the approximate location of the disk fragment as compared with the fragments in Stookey's group producing cord compression.

All the operations in this series were performed under general anesthesia. Consequently we have no experience with the determination of the level of the lesion by pressure on the yellow ligament and subsequent novocain injection, as suggested by Semmes and Murphey. Their procedure may be the method of choice in cases suitable for local anesthesia.

SUMMARY AND CONCLUSIONS

Eight cases of herniation of the nucleus pulposus in the lower cervical spine are reported. There were lesions at the fifth cervical interspace in 4 cases, at the sixth in 3 and at the seventh in 1, with involvement of the sixth, seventh and eighth cervical roots, respectively.

The clinical data were brought together in a syndrome that comprised root pain and local sensory and motor disturbances, as well as positive x-ray, cerebrospinal-fluid and lipiodol findings.

The distribution of the sensory abnormalities was compared with standard dermatome charts. In these cases the sixth cervical dermatome seemed to involve the scapula, the anterolateral aspect of the upper arm, the antecubital space, the radial forearm and its thumb and index finger. The seventh cervical dermatome seemed to involve the scapula.

FIGURE 2. Diagram Showing Various Types of Herniation of the Cervical Disk.

The three types are as follows. 1—herniation producing cord compression; 2—herniation producing unilateral compression of the ventral root (Stookey's Group II); and 3—herniation producing bilateral compression of the ventral roots (Stookey's Group I).

tracts and roots took place. The other patients were relieved of their pain dramatically. The recovery of muscle function, if impaired, was gratifying.

the posterolateral aspect of the upper arm, and the dorsal surface of the forearm and the index and middle fingers. The eighth cervical dermatome seemed to involve the scapula, the inner and upper arm, the forearm and the little finger.

The importance of a systematic neurologic examination in cases with pain or disability of shoulder and arm is emphasized, to separate the apparently specific syndrome of cervical herniations of the nucleus pulposus from other extraspinal and intraspinal entities.

The results of the removal of the disk fragments by laminectomy — more recently by subtotal hemilaminectomy — were good.

The clinical data of 3 cases included in this paper were obtained through the courtesy of Drs J. S. Hodgson, T. J. Putnam and J. C. White.

SEROLOGIC TYPES OF HEMOLYTIC STREPTOCOCCI ISOLATED FROM SCARLET FEVER IN MASSACHUSETTS, 1942-1943*

LIEUTENANT S. M. WHEELER (MC), U.S.N.R.† AND G. E. FOLEY‡

BOSTON

DURING 1942 and 1943, hemolytic streptococci isolated from the throat swabs of patients with scarlet fever admitted to various Massachusetts hospitals were classified as to serologic type. The laboratory studies were carried out at the Department of Preventive Medicine, Harvard Medical School,§ and arrangements for the provision of throat cultures were made possible through the cooperation of the Division of Communicable Diseases of the Massachusetts Department of Public Health.¶

In this period a total of 631 throat swabs were examined, of which 427 (67.7 per cent) were positive for Group A hemolytic streptococci. The low percentage of positive cultures from scarlet-fever cases can be explained in part by the loss of viability of organisms sent through the mail. These strains were

classified as to serologic type by the method of Griffith.¹ Slide agglutination was facilitated by the digestion of granular or self-agglutinating cultures by the tryptic digest method described by Allison.²

The serologic types of hemolytic streptococci isolated from scarlet-fever cases in different localities are presented in Table 1. The similarity of the predominant types of streptococci causing this disease in these various localities is noteworthy. In Table 2 the most frequent scarlet-fever types in two earlier Boston studies are compared with those encountered in the Massachusetts communities in 1942 and 1943, which are represented by community in Table 1. It is not possible to draw conclusions from these data concerning the limits of constancy of the streptococcus-type pattern in scarlet fever, but the emergence of certain predominant types and the tendency of others to decline or disappear can be seen.

The available data suggest that during the period of seasonal prevalence of streptococcal infection certain types maintain themselves as the cause of scarlet fever in a large proportion of cases. From these studies it is obvious that in Massachusetts the type pattern in scarlet fever varies from year to year. Further observations are necessary to determine the number of years that single types continue to occur predominantly in scarlet fever. There is a suggestion that Type 2 has maintained

¶We limit the limits of laboratory facilities, it is possible for this laboratory to type hemolytic streptococci from scarlet fever and other infections occurring in the New England area. Swabs or cultures submitted should be accompanied by the patient's name and address, age, sex, date of onset of disease, date of culture, source of swab or culture and diagnosis and treatment (if any), together with the sender's name and address so that the results may be reported.

We are indebted to Dr. R. F. Feemster, director of the Division of Communicable Diseases, Massachusetts Department of Public Health, for making arrangements to carry on this study.

itself as a major cause of the disease during the months of high seasonal prevalence in both 1942 and 1943.

Evidence has accumulated in the literature that all the thirty or more well-established types have been found in scarlet fever. This is borne out by laboratory studies indicating that the common erythrogenic toxin, the so-called "N.Y.-5," is broadly valent over various serologic types in Group A

an infection without rash from a case of scarlet fever and in turn transmit the infection to contacts in whom illness manifests itself in a rash only if they have a low immunity to the Dick toxin.

This variety of clinical manifestation is best observed in milk-borne or food-borne outbreaks of streptococcal infections caused by one strain or type infecting from a common source. The work of Stebbins, Ingraham and Reed⁸ and of Dublin et al⁹

and certain Group C strains of hemolytic streptococci.⁵ The quality of toxigenicity is apparently a characteristic easily acquired or lost. Although the circumstances that favor the production of erythrogenic toxin by a given strain are not yet known, epidemiologic observations suggest that types vary in their production of toxin from time

on milk-borne sore throat and scarlet fever reveals the importance of the antitoxic immunity of the host in determining the presence or absence of a rash in the resulting infection. Secondary cases in the same household may also show these characteristics. Table 3 shows the types of hemolytic streptococci isolated from multiple cases in the same family in

to time and from place to place. The appearance of predominant type patterns suggests that locally and temporally certain types are the most successful rash producers. The streptococcus types predominant in scarlet fever can be compared in epidemiologic behavior with the pneumococcus types most frequently associated with pneumonia.

A type study of scarlet-fever streptococcus strains in regions such as Massachusetts reveals that in addition to the predominant types, a variety of other strains are at times found in the admission cultures of patients. This serves to emphasize the essential unity of scarlet fever with other streptococcal infections. The appearance of a rash in a person with hemolytic streptococcus infection depends on the toxigenicity of the organism, a property that is present in varying degree in many types, and susceptibility of the host to this toxin, as indicated by the positive Dick test. As Gordon^{6,7} has pointed out, a Dick-negative subject may contract

this study. Infections without rash did not appear with scarlet-fever infections in this series. The cultures were submitted from contagious-disease hospi-

tals, which are apt to admit patients with streptococcal infection only if a rash is present, in accordance with the usual public-health administrative

cedures. Undoubtedly a periphery of persons with nonscarlatinal infection was associated with these hospitalized family cases but were themselves not admitted to the hospital. The consistency of type in the infecting organisms from secondary cases in the same household, as shown in Table 3, seems to confirm that these secondary cases are the result of true household exposure.

The study of the distribution of streptococcus types in scarlet fever raises the question of the relation of the type pattern to the epidemiologic and clinical features of the disease. Relatively few data

Balkan countries scarlet fever was in an epidemic phase in which Type 10 was a highly effective invader and rash producer. In England, the disease may be more in an endemic or perhaps interepidemic phase, with four effective strains, Types 1, 2, 3 and 4, causing most of the disease, yet with no one of these types acting as a truly epidemic strain on a wide scale. Patterns differ in other countries, and in North America the typing evidence suggests a sporadic appearance of predominant scarlet fever types. It may be that the relative mildness of the disease in recent years in this country is reflected in the variety

are available from North America on streptococcus typing. Table 4 gives the available information on scarlet-fever types from the literature and from unpublished work in the United States and Canada. These data may be compared with those from Great Britain, where extensive study carried on since 1926 shows that Types 1, 2, 3 and 4 cause at least half the cases of scarlet fever but vary from year to year in their relative frequency.^{10, 11} Studies over a period of five years in Rumania and other eastern European countries show that the most constant high percentage of scarlet fever is caused by Type 10, although there are fluctuations in relative preponderance.¹² It may be that during these years in the

of types associated here with scarlet fever. On the other hand, the emergence of a single type associated with a high percentage of cases may be an indication of scarlet fever in a severe epidemic form.

The geographic limits of a type pattern in scarlet fever are yet to be defined. There is some suggestion from Table 4 that the patterns are fairly widespread. Other studies on throat cultures in normal population groups show similarities of streptococcus-type patterns that fluctuate only in relatively large units of time and space.²⁷

Circumscribed outbreaks such as occur in institutions or from such accidents of environmental sanitation as the contamination of raw milk may not

itself as a major cause of the disease during the months of high seasonal prevalence in both 1942 and 1943.

Evidence has accumulated in the literature that all the thirty or more well-established types have been found in scarlet fever. This is borne out by laboratory studies indicating that the common erythrogenic toxin, the so-called "N.Y.-5," is broadly valent over various serologic types in Group A

an infection without rash from a case of scarlet fever and in turn transmit the infection to contacts in whom illness manifests itself in a rash only if they have a low immunity to the Dick toxin.

This variety of clinical manifestation is best observed in milk-borne or food-borne outbreaks of streptococcal infections caused by one strain or type infecting from a common source. The work of Stebbins, Ingraham and Reed⁸ and of Dublin et al⁹

and certain Group C strains of hemolytic streptococci.⁵ The quality of toxigenicity is apparently a characteristic easily acquired or lost. Although the circumstances that favor the production of erythrogenic toxin by a given strain are not yet known, epidemiologic observations suggest that types vary in their production of toxin from time

on milk-borne sore throat and scarlet fever reveals the importance of the antitoxic immunity of the host in determining the presence or absence of a rash in the resulting infection. Secondary cases in the same household may also show these characteristics. Table 3 shows the types of hemolytic streptococci isolated from multiple cases in the same family in

to time and from place to place. The appearance of predominant type patterns suggests that locally and temporally certain types are the most successful rash producers. The streptococcus types predominant in scarlet fever can be compared in epidemiologic behavior with the pneumococcus types most frequently associated with pneumonia.

A type study of scarlet-fever streptococcus strains in regions such as Massachusetts reveals that in addition to the predominant types, a variety of other strains are at times found in the admission cultures of patients. This serves to emphasize the essential unity of scarlet fever with other streptococcal infections. The appearance of a rash in a person with hemolytic streptococcus infection depends on the toxigenicity of the organism, a property that is present in varying degree in many types, and susceptibility of the host to this toxin, as indicated by the positive Dick test. As Gordon^{6,7} has pointed out, a Dick-negative subject may contract

this study. Infections without rash did not appear with scarlet-fever infections in this series. The cultures were submitted from contagious-disease hospi-

POLYARTHRITIS IN SICKLE-CELL ANEMIA*

H. G. BRUGSCH, M.D.,† AND DOROTHY GILL, M.D.‡

BOSTON

SICKLE-CELL anemia has long been known to simulate rheumatic fever. Huck¹ was the first to describe cardiovascular involvement in this form of anemia, and King and Janeway² have emphasized electrocardiographic changes similar to those found in rheumatic fever, such as prolongation of the PR interval. Klinefelter,³ in a summary of the present knowledge of the heart in sickle-cell anemia, noted at autopsy the absence of valvular disease in patients who had died of sickle-cell anemia and heart failure. Although on the whole little attention has been paid the heart pathologically, mention has been made of myocardial scars, flabbiness of the muscle and enlargement of the right ventricle (Bauer⁴).

Despite the fact that the high incidence of combined cardiovascular disease, joint pain and fever in sickle-cell anemia is stressed in publications from the South (Wintrobe⁵ and Bauer⁴), the frequent occurrence of these symptoms in Negroes living in the northern states has attracted scant attention. Because of the prevalence of true rheumatic fever in Whites as well as in Negroes in the North, the diagnosis of rheumatic fever is always uppermost in the mind of the physician when a young Negro complains of joint pains in a febrile disease of unknown etiology. This is particularly regrettable since sickle-cell anemia, once considered, can be easily demonstrated by a sealed wet preparation of the blood. In 3 of the 4 cases reported herein the correct diagnosis was missed because such preparations were not made. Wet preparations should, therefore, be included in the examination of any Negro with symptoms suggesting rheumatic fever, regardless of the presence or absence of anemia. In one of the patients (Case 3), sickle-cell anemia was considered and wet preparations were studied. When sickling did not occur after twenty-four hours, the diagnosis was abandoned. Further studies revealed that in this case the tendency to sickle did not appear until forty-eight hours had elapsed, and it was later found necessary to observe these preparations for at least ninety-six hours.

The following is a summary of 4 cases of sickle-cell anemia found among 16 Negroes whose illness had been erroneously diagnosed as active or inactive rheumatic fever.

CASE REPORTS

CASE 1. T. L., a 12-year-old Negress, at the age of 5 began to have prolonged episodes of low-grade fever, frequently associated with shorter periods of pain in the muscles and joints. At other times she had vague abdominal pain. In

July, 1941, when such an episode was observed by the district physician, a diagnosis of rheumatic fever was made. After 1 month of bed rest an inconstant, soft systolic murmur was heard at both apex and base. The patient returned to school 5 months later and was seen regularly in the Out-patient Department, where a wet preparation of the blood showed sickling after 96 hours. Some weeks later, the sickling was found to be immediate. The heart was normal by x-ray. The electrocardiogram showed sinus arrhythmia, with P₁ and P₂ upright, P₃ inverted, a PR interval of 0.12 second, a QRS complex of 0.06 second, T₁ upright and T₂ inverted, thus being within normal limits for this age. The lowest hemoglobin found was 67 per cent, the lowest red-cell count 3,570,000 and the white-cell count 6500. The blood sedimentation rate was normal.

CASE 2. J. H., a 12-year-old Negress, at the age of 7 was found to have a cardiac murmur. At times she had pain in the thighs. Intermittent icterus of the scleras, not associated with other signs of illness, had been observed by the mother since the age of 9. In 1939, the patient was hospitalized because of an attack of acute abdominal pain, considered by her physician to be caused either by appendicitis or by rheumatic fever. A blood test, however, showed sickling, and a diagnosis of sickle-cell anemia was made. Thereafter the patient was not again under medical observation until March, 1942, when she was examined for acute pharyngitis. A rough apical systolic murmur was heard at that time. A wet preparation of the blood showed marked sickling. The blood sedimentation rate was normal (3.5 mm. per hour). X-ray examination of the chest showed the heart to be definitely enlarged to the left. The electrocardiogram read as follows: P and T upright, Q 3 mm., QRS complex normal, PR interval 0.18 second and Lead 4 normal. The hemoglobin was 57 per cent, the red-cell count 2,700,000, and the white-cell count 15,000, with 46 per cent polymorphonuclear leukocytes, 22 per cent lymphocytes, 13 per cent monocytes, 18 per cent eosinophils, and 1 per cent basophils. The icteric index was 25.

CASE 3. B. M., a 27-year-old Negress, enjoyed fairly good health until the age of 25, when she suddenly developed fatigue, dyspnea on exertion and dizziness. Because of a history of "rheumatism" 10 years before, a blood pressure of 155/105 and a short, rough apical systolic murmur, a diagnosis of rheumatic heart disease was made. Anemia was present at that time, — the red-cell count was 4,550,000 and the hemoglobin 55 per cent — but was attributed to a persistent menorrhagia. A blood Hinton test was negative, although 4 years previously the patient had contracted syphilis and had received 12 months' treatment. Ferrous sulfate caused moderate improvement, both symptomatically and in the blood picture. The patient ceased coming to the clinic after 4 months. On readmission 1 year later, hypochromic anemia and hypertension were again present. A wet preparation of the blood showed sickling. The hemoglobin was 50 per cent, the red-cell count 4,080,000, and the blood sedimentation rate 20 mm. per hour. An electrocardiogram showed sinus rhythm with ventricular extrasystoles. P₁ was flat. P₂ and P₃ upright, T₁ flat, T₂ and T₃ low, and R₄ inverted; the PR interval was 0.20 second, and the QRS complex 0.06 second. This was considered suggestive of myocardial damage. X-ray examination showed a normal outline of the heart.

CASE 4. L. D., a 28-year-old Negress, was first seen because of headaches of long standing. She stated that she had had two episodes of moderate joint pain without swelling 3 and 10 years previously, but did not recall whether fever had been present. Physical examination revealed a normally developed girl with definite pallor but no jaundice of the mucous membranes. The joints were normal. There was dyspnea on moderate exertion, and at the apex there was a loud Grade II systolic murmur, transmitted to the axilla. The heart was not enlarged either by percussion or x-ray; the rhythm was regular and the blood pressure 110/60. A

always be caused by the prevailing types in the community. In the same way, closely herded communities, such as Army and Navy training stations may show predominating types different from those of the surrounding population. Such differences between military and civilian types may have epidemiologic importance at the present time. If the semi-isolated military community finds scarlet fever and streptococcal disease caused by the same types as in the surrounding population, the problem of control is shared with those outside. If the streptococcus-type flora is indigenous to the camp, the indications for control lie in the environment within the compound.

SUMMARY

Types of hemolytic streptococci associated with scarlet fever in certain Massachusetts cities during 1942 and 1943 were predominantly Types 2, 1, 8 and 19 in that order of frequency. During this period there was some shifting of type in relative order of frequency among the predominant types, although Type 2 maintained itself as a major cause of scarlet fever.

MEDICAL PROGRESS

RECENT ADVANCES IN SURGERY (Concluded)*

ALFRED BLALOCK, M.D.†

BALTIMORE

HYPERPARATHYROIDISM

THE first successful operation for removal of a parathyroid tumor was performed by Landl,³⁴ of Vienna, in 1925. This patient had von Recklinghausen's disease, and improvement in the condition of the bones followed. This observation was instrumental in altering the previously held concept that the parathyroid enlargement was secondary to the disease of the bones. The view was then held for several years that the parathyroid hormone acted primarily on bone and that any significant disorder of hormone production must result in changes in the bones. Following the preparation of parathyroid extract by Collip, the pathologic physiology of hyperparathyroidism could be approached and was clarified. The working out of the clinical picture was done at the Massachusetts General Hospital by Albright, Aub, Bauer and others, and the frequent association of urinary calculi with hyperparathyroidism was noted and studied. These and other observations led to the establishment of the fact that the disorder in hyperparathyroidism is primarily one of metabolism.

As a result of careful diagnostic studies by the medical staff and of the excellent procedures devised by Churchill and Cope for identification and removal of abnormalities of the parathyroid glands, 67 patients³⁵ with a proved diagnosis of hyperparathyroidism were operated on at the Massachusetts General Hospital in the years 1932 to 1942. The majority of these patients had renal calculi and no demonstrable disease of bone. As to the frequency of hyperparathyroidism in association with renal stones, the following statement of Cope³⁶ is of interest:

Both Fuller Albright and I are agreed in the impression that approximately 15 per cent of patients with renal stones in this part of our world have hyperparathyroidism as the cause of these stones. In only a few of these cases is the disease so marked that it can be picked up either by presence of bone disease or by one blood examination. Persistent effort and care are necessary to weed out the patients with hyperparathyroidism. A number of blood examinations have to be made and the patient is often followed for quite a while before the diagnosis is finally established.

The surgical treatment of this disorder will not be discussed in detail, but it is well to emphasize the fact that the problem is concerned with the site

as well as the size of the tumor or hyperplasia. The parathyroid glands, whether adenomatous, hyperplastic or uninvolved, have been found in various locations between the larynx and the heart. In approximately 20 per cent of the cases at the Massachusetts General Hospital the adenoma has been in the anterior or posterior mediastinum. The procedure recommended by Cope³⁷ is as follows: At the first stage the neck and the posterior mediastinum are explored through a supraclavicular incision. If the offending gland or glands are not found, the anterior mediastinum is explored through a median sternotomy at another operation. It is well to remember that all the glands may be hyperplastic. Visualization of the parathyroid glands in such cases should be followed by total removal of three and subtotal resection of the fourth. The finding of one adenoma does not mean that others may not be present. It is desirable whenever possible to locate all the glands.

The mortality rate with this operation has been low and the results in general have been excellent. Cope³⁶ states that there has been no further formation of stones in the urinary tract in patients with corrected metabolism. In patients with lesions of bones, a thick wall of bone is deposited around the cyst so that the bone is strengthened but the cyst does not disappear. In addition, several patients with severe anemia have shown decided improvement. The development of this entire subject represents a brilliant accomplishment, particularly on the part of the staff of the Massachusetts General Hospital.

THE THYMUS GLAND AND MYASTHENIA GRAVIS

Nothing is known about the function of the thymus gland and little about the pathogenesis of myasthenia gravis. It is known that a significant percentage of patients with myasthenia gravis have been found by roentgenography, operation or autopsy to have a tumor of the thymic region. The lesion is usually benign, and is rare in patients who do not have myasthenia gravis.

The results that followed the removal of benign thymomas from patients with myasthenia gravis encouraged Harvey, Ford, Lilienthal and myself³⁸ in July, 1941, to determine the effect of total thymectomy without regard to the presence or absence of a tumor. This was the first time that the effect of total removal had been studied in man. Since July, 1941, we have removed the thymus gland

†Surgeon-in-chief, Johns Hopkins Hospital; professor of surgery, Johns Hopkins University School of Medicine.

few rales were present over both lung bases. The hemoglobin was 65 per cent, and the red-cell count 3,560,000, and the white-cell count 15,000, with 58 per cent polymorphonuclear leukocytes, 25 per cent lymphocytes, 14 per cent monocytes, 2 per cent eosinophils and 1 per cent basophils. The blood sedimentation rate was 5.0 mm. in 1 hour. Blood Hinton and Wassermann tests were negative. A catheterized urine specimen contained 0.05 per cent of albumin. Blood smears revealed moderate sickling in stained and marked sickling in wet preparations after several hours.

DISCUSSION

Three of these 4 patients had had more or less severe joint pain in the past, but in none was there any residual damage in the joints. Vague muscle pain in the thighs and arms, unassociated with actual joint pain, had also been present. Since none of the patients were observed during an acute febrile episode with joint pain, it was impossible to check on the observation of others that salicylates, in contrast to their effectiveness in acute rheumatic fever, have only slight analgesic effects in sickle-cell anemia.

At the time of examination signs of cardiac embarrassment were not present except for slight dyspnea on exertion in Cases 3 and 4. One physical finding suggesting mitral-valve disease was present in all patients, namely, a loud systolic murmur, localized over the apex and transmitted to the axilla. In 3 patients, the murmur was louder than one would expect from the degree of anemia present; a thrill was not present. Slight enlargement of the left ventricle was present in 2 patients. A diastolic murmur was not heard in any patient but has been reported by Klinefelter³ and others. A systolic murmur over the aorta was present in Case 4. Slight prolongation of the PR interval was found in Case 4, and the general electrocardiographic picture was that of myocardial damage.

All the patients showed marked hypochromic anemia not responding to iron. The blood sedimentation rate was normal in 3 patients and slightly elevated in 1. Although this was not ascertained during acute attacks, a normal rate, if found during relapses, may prove of great aid in ruling out acute rheumatic fever. Such a rate is in conformity with experiments conducted by Bunting,⁶ who showed that sickle-shaped erythrocytes do not settle so fast as do normally shaped ones. In

sick ones, elevated blood sedimentation rates have been observed.

Although only the diagnosis of sickle-cell anemia alone could be established in our cases, the possibility of a combined occurrence of rheumatic fever and sickle-cell anemia should be kept in mind. In the absence of a mitral diastolic murmur, enlargement of the heart (mainly to the left) without characteristic configuration and a slow sedimentation rate, there is little likelihood of the presence of rheumatic fever. According to experienced observers, such a coincidence is extremely rare. Klinefelter³ mentions only one doubtful case. Walker and Murphy⁷ recently published a case verified by autopsy. Such a combination should be kept in mind, although for practical purposes it is improbable.

The well-known observation that heart failure frequently occurs in sickle-cell anemia remains to be explained. Most patients die either from heart failure or multiple thromboses. The tendency to thrombosis may lead to coronary occlusions, and the presence of myocardial scars in such cases may be due to myocardial damage following arterial thrombosis. Bauer⁴ stresses the frequency of right-sided failure due to thrombosis of the pulmonary vessels. Several such cases with terminal cor pulmonale are on record.⁸

SUMMARY

Four cases of sickle-cell anemia are discussed in which the diagnosis was obscured by the presence of polyarthritides and heart murmurs simulating rheumatic fever.

It has long been known that a saccular aneurysm that is filled with clot — "Nature's cure" — may remain inactivated indefinitely. Blakemore and King have pointed out that blood circulating under pressure creates a strain on the wall of a saccular or fusiform aneurysm that varies with the square root of its surface area. A doubling of the diameter of an aneurysm by growth increases the total strain on the sac wall by 100 per cent. On the other hand, a blood clot, behaving according to the physical laws governing solids, reduces the strain on the sac wall of an aneurysm in strict accordance with the amount of fluid blood it displaces. The degree of clotting obtainable in an aneurysm depends, other things being equal, on the rate of blood flow through the aneurysm and the presence of an abundant clot-stimulating surface. Measurements of rate of flow in saccular aneurysms of equal size may vary as much as 300 per cent depending on the size of the mouth.

In the Blakemore and King's electrothermic method of coagulating aneurysms, fine, insulated coin-silver wire is introduced through a needle into the aneurysm in 10-meter segments. The protruding ends of a segment are connected with a direct current so regulated and calibrated against changes in electrical resistance of the wire on heating as to afford an accurate measurement of the temperature of the wire at all times and the rate of blood flow through the aneurysm on initial heating. Each segment of wire is finally heated to 80°C., which results in the deposit of a tenacious clot. On the basis of the number of amperes of current required to heat the first 10-meter segment to 80°C., it is possible to determine the variety of aneurysm (based on rate of flow) and approximately the number of segments that will be necessary to impede the blood flow to the point of occurrence of mass clotting. Blakemore and King have arteriographic evidence and proof from autopsy examinations that "brim-full" clotting can be obtained by this method in saccular aneurysms in which the diameter of the mouth does not exceed that of the sac. Experience so far has shown that this group behaves clinically as do cases of "Nature's cure." Experience with the method in treating syphilitic aneurysm of the thoracic aorta of the high-velocity, cup-shaped, saccular and fusiform varieties, although not showing a cure, indicates that clotting is frequently obtained to the degree of relieving strain on the sac sufficiently to permit the strengthening processes within the sac wall an opportunity to become effective. Particularly is this true in patients under forty-five years of age who are relatively free of arteriosclerosis. This is attested by the fact that several patients have remained symptom free for several years spent at hard labor in shipyards and munition factories. Aneurysms of the abdominal aorta of this type, including the arteriosclerotic fusiform aneurysm, may be inactivated by occluding the

aorta from within by wiring in two or more operative stages. The method affords a means of controlled clotting for gradual obliteration of the arteriosclerotic popliteal aneurysm without the complication of gangrene.

In the five-year period 1935 to 1940, Blakemore⁴⁶ used his method on 26 patients with syphilitic aortic aneurysm. Nine of these patients are alive, an average interval of seven years having elapsed since the operative procedure. The thoracic aorta was affected in 7 cases and the abdominal aorta in 2. Survival periods of the remaining patients ranged from a matter of hours up to eight years. The patient who survived for the full eight years had a fusiform aneurysm of the ascending aorta; he worked in a munition plant until four weeks preceding death, which was due to bronchial erosion and infection, with secondary hemorrhage. Following the wiring procedure nearly all the patients were relieved of their pain. In the absence of infection there has been only one rupture of the sac following the wiring in Blakemore's total series of more than fifty aortic aneurysms.⁴⁶ This is in sharp contrast to the high incidence of rupture — approximately 30 per cent — that accompanied the employment of the previous methods. Since poor risks were not excluded and since the patients had an associated syphilitic infection that in itself might have been fatal, the results appear to be encouraging. It is obvious that procedures such as blocking the sympathetic nerves should be used in association with the wiring procedure when indicated.

It should again be emphasized that the Blakemore operation is not the procedure of choice in all cases; for example, most peripheral syphilitic aneurysms should be treated by the Matas method. In summary, wiring and electrothermic coagulation may be used to inactivate syphilitic saccular aneurysms of the aorta, to slow the growth of high-velocity, cup-shaped and fusiform aneurysms of the thoracic aorta and to cause total occlusion of aneurysms of the abdominal aorta as well as to treat some of the peripheral ones.

BLOOD-VESSEL ANASTOMOSES

In the present war better means for preventing and controlling infection have made it safer to defer the amputation following injuries to extremities until the nutritional status of the part can be determined. Unfortunately, a number of the reports thus far show that the incidence of gangrene is higher than it was in the last war. This is probably due in the main to the more severe injuries that result from the destructive agents that are being employed. Although sympathetic block is of some value in increasing the circulation to an extremity in which the main vessels have been severed, there is frequently serious damage to the collateral vessels as well, and the benefit that results from blocking the sympathetic nerves and from the use of papav-

from 20 patients with *myasthenia gravis*. Only 2 of these patients had a thymoma. The results may be divided into five groups.

Four patients have died since the operation. In 3 cases death occurred within four days. In 2 of these, the patients were extremely ill at the time of operation and the procedure was carried out as a last resort. One patient died eight months after the operative procedure, having shown no improvement as a result of it.

Three of the remaining 16 patients are well or essentially well. Two of these have shown sustained improvement for more than two and a half years. One of the 3 patients had a thymoma.

Five patients are considerably improved. The dose of prostigmine has been very much reduced and the patients' general condition is much better than it was previously.

Five patients have shown slight improvement.

Three patients have exhibited little or no improvement.

The experience of Keynes and Carson³⁹ has been similar to ours. At the time of their report in 1943, thymectomy had been performed on 12 patients, and it is said that the series has now been extended to 25 cases.

Since some patients with *myasthenia gravis* have spontaneous remissions and since the results following thymectomy are not uniform, it is difficult to judge of the effects of this operative procedure on the course of the disease. The impression is gained that the removal of the thymus gland has been the cause for the improvement in a number of cases. Unfortunately, there are at present no means available for determining preoperatively which patients will be benefited by the procedure. Until further information is available, it appears that thymectomy should be performed only on patients with a severe degree of *myasthenia gravis* in whom the response to prostigmine medication is unsatisfactory.

PATENT DUCTUS ARTERIOSUS

Although it has been only a few years since Gross^{40,41} first successfully occluded a patent ductus arteriosus, the procedure has been accepted without reservations and is a noteworthy accomplishment. That this lesion is not a rare one is demonstrated by the fact that Gross³⁰ alone has operated on 65 persons with this abnormality. In fact, Keys and Shapiro⁴² estimate that there are approximately 20,000 people in the United States with an open ductus.

Since it has been demonstrated that this operative procedure can be performed with a low mortality rate, the indications for operation have been somewhat extended. The most conservative probably agree with Gross³⁰ that there are at least three definite indications for operation: when the patient

is not developing properly in physical stature; when there is any evidence of cardiac fatigue; and when there is superimposed *Streptococcus viridans* infection without evidence of peripheral emboli. Credit is due Touroff⁴³ for his work in establishing the value of operation in patients with endarteritis. In addition to the above-mentioned three groups, there remains a group of patients who are getting along well except for the constant danger of a future infection with *Str. viridans*. It is estimated by Gross³⁰ that such patients face a risk possibly high as 25 per cent of having a serious infection in the future. In addition to the danger of endarteritis, the open ductus in such patients may be causing symptoms that are not noted. The studies of Keys and Shapiro⁴² show that patency of the ductus arteriosus after the age of seventeen is associated with an average reduction in life expectancy about twenty-five years. Gross³⁰ has this to say about the results of operation on those patients who have been relatively free of symptoms:

I have been increasingly impressed by the statements of some of these patients after operation. Many of them have volunteered the information that . . . whereas they had no complaints before operation, . . . they now feel much better than they did previously; they have an increased vigor, their breathing is easier, their energy is greater and so forth. In other words, their circulation has been improved and they have become conscious of the change.

The frequency with which this operative procedure will be performed in the future will be influenced to a considerable extent by the success or failure of penicillin or some similar agent in the treatment of infection due to *Str. viridans*. Even if such infection does respond to penicillin, there will still be many patients with a patent ductus in whom operation is indicated.

From the viewpoint of operative technique, the main question at present is whether one should simply ligate the ductus or whether it should be completely divided and closed. Gross⁴⁴ now favors the latter course. Division and closure of the ductus is a better surgical procedure, but at the same time is a difficult and rather dangerous operation.

WIRING AND ELECTROTHERMIC COAGULATION OF ANEURYSMS

It has been approximately eighty years since the first attempt was made to wire an aneurysm, and has been fifty-six years since Matas first performed his procedure known as "endo-aneurysmorrhaphy." As regards improvements in methods for wiring aneurysms, the advances that have been made by Blakemore and King⁴⁵ have not been fully appreciated. Their procedure is so different from that used previously that it cannot be considered in the same class, and this contribution rates as one of the greatest in surgery in the last decade. All aortic aneurysms should be treated by this method as should peripheral aneurysms on an arteriosclerotic basis in the older age group.

completely interrupted; otherwise the secretion of sympathin at their endings is capable of exciting contraction in all the denervated smooth-muscle cells in the vascular walls. Smithwick⁵⁴ has described an excellent method for preganglionic sympathectomy of the arm and for the prevention of regeneration. He advises division of the chain below the third thoracic ganglion and intradural division of the second and third thoracic anterior spinal roots so that their subsequent growth will be checked by the intact dura. The mobilized upper portion of the trunk is covered with a cylinder of fine silk and the free end is transplanted into the muscles of the back in order to prevent reconnection of the divided ends. Despite all precautions, recurrence of vasoconstrictor tone occasionally takes place, but it can be stated that the results are much better now than previously.

Other types of vascular disease. In occlusive vascular disease of the extremities there may be superimposed vasospasm that is the deciding factor in leading to gangrene. It is important to realize that sympathectomy may bring about decided improvement even though preliminary tests do not indicate that such would be the case. Trimble,⁵⁵ Shumacker⁵⁶ and others have reported the cases of a number of patients with uncomplicated arteriosclerosis who have been benefited by sympathectomy. There is frequently a large element of vasospasm in thromboangiitis obliterans, and sympathectomy is often helpful. This procedure may be combined with the crushing of peripheral nerves. The use of sympathetic block in the treatment of thrombophlebitis was considered by Ochsner⁵⁷ in a previous Shattuck Lecture. Ligation of the major arteries of extremities had best be accompanied by measures that result in a local abolition of vasoconstrictor tone. In this manner the incidence of gangrene can be greatly lessened.

Sympathectomy in Essential Hypertension

Even though sympathectomy has distinct limitations in the treatment of hypertension, there is no doubt that there are many patients who have been definitely benefited. Only an occasional patient over fifty years of age is a suitable candidate for this procedure. Sympathectomy should not be performed when both cardiac and renal functions are significantly impaired. Grimson⁵⁸ has pointed out that the lowering of the blood pressure is usually directly proportional to the extent of the sympathectomy and inversely proportional to the severity of the disease. Four general types of operative procedures are in current use: supradiaphragmatic ganglionectomy and splanchnicectomy, as described by Peet⁵⁹; the subdiaphragmatic operation of Allen and Adson⁶⁰; the combined thoracolumbar sympathectomy of Smithwick⁶¹ and the total sympathectomy of Grimson.⁶² The first two procedures do not completely denervate the lower part of the body.

There has not been sufficient experience as yet to determine whether the more radical procedure of Grimson produces better results than does that of Smithwick. The latter procedure has yielded excellent results, and at present it appears to be the operation of choice. No doubt Smithwick's good results can be explained in part by a careful selection of patients.

Despite much work in recent years on the etiology of hypertension, understanding of the condition in man remains extremely inadequate. There is not even certainty as to the manner in which sympathectomy exerts its beneficial effects. The likeliest explanation is that there is a general reduction of the tone of smooth muscle in the denervated vascular bed.

THE PANCREAS

In the past the main deterrent to operations on the pancreas was the unfounded but firm conviction on the part of surgeons that operative trauma to the pancreas was fraught with great danger of producing acute pancreatitis, which in itself entailed a high mortality. It is indeed difficult to understand how this conception gained such widespread adoption in view of the fact that throughout the past decades cases of incision of the pancreas with excision of tissue, but without the production of pancreatitis, were reported in the literature from time to time.

Recent years have witnessed the development of the surgery of pancreatic tumors. The surgery of pancreatic inflammations has received relatively less attention because of the rarity of these conditions. The advent of the blood amylase test for acute pancreatitis has resulted in an improvement in diagnosis. Experience indicates that acute primary hemorrhagic pancreatitis is probably best treated conservatively rather than by operation and drainage of the region, as was the custom in the past when such a diagnosis was made.

In regard to the surgery of pancreatic tumors, the important factors in its development were the description of the syndrome of hyperinsulinism due to islet-cell adenomas and the spectacular cures obtained by their excision; the ever-increasing boldness of surgeons in extending surgical attack on intra-abdominal cancer, and the realization that survival is possible in man without the duodenum and the head of the pancreas, with consequent occlusion of external pancreatic secretion. As regards the second of these factors, advances in the understanding of surgical shock, the use of vitamin K and an appreciation of the importance of the nutritive state of the surgical patient have contributed to the feasibility of procedures that formerly could hardly have been carried out.

The following are a few of the many important contributions to this subject: the description of hyperinsulinism by Harris⁶³ in 1924; the report by Wilder and his associates⁶⁴ in 1927 of the first case of insulin-producing islet-cell carcinoma, which was

erine is not sufficient to prevent gangrene. The importance of this problem of gangrene and amputation has been appreciated by Blakemore and his associates, and their studies on this subject are of great interest. Eighty per cent of all wounded men in World War I had injuries of the extremities, and the extensive use of land mines and fragmentation shells at present indicates that the incidence in this war will continue to be high.

Blakemore, Lord and Stefko^{47, 48} have devised a nonsuture method for anastomosing the ends of severed arteries that consists in using vitallium tubes as a prosthesis for vein grafts. Long defects in vessels may be bridged. The method is simple and the anastomosis can be performed quickly. A moderate disproportion between the diameter of the vein graft and that of the artery does not prevent a successful result. It has been shown that preserved veins that have been prepared by quick freezing in a mixture of alcohol and dry ice and kept in the frozen state function effectively as grafts. Furthermore, homotransplants of vein grafts as well as autotransplants serve to prevent the development of gangrene.

Blakemore, Lord and Stefko⁴⁷ have had remarkable success in the experimental use of their method in conjunction with débridement and chemotherapy in badly contaminated wounds. The severed femoral arteries of dogs were repaired by use of the vein graft twenty-four hours after the vessels had been ligated and divided without aseptic precautions. Despite the fact that contamination was present and that anticoagulants were not used, 85 per cent of the anastomoses remained patent. Clinical experience with the method has confirmed the experimental observations. The relative freedom of the method from complications is thought to be due to the nonirritating qualities of the vitallium and to the fact that, since no sutures are used, the flowing blood comes into contact only with intima. It is evident that many extremities that would otherwise be lost can be saved by the employment of this method.

Blakemore⁴⁹ emphasizes the importance of including the use of heparin in the program for handling the wounded extremity with damage to the main artery. After good hemostasis has been obtained, preferably without the use of a tourniquet, measures for the control of blood clotting should be instituted in order to preserve the patency of undestroyed collateral vessels. These measures include the injection of 10 mg. of heparin—together with 50,000 units of penicillin—into the distal end of the severed and ligated main artery and the subcutaneous injection of 150 mg. of heparin in Pitkin's menstruum (Loewe's method). The clotting time is thereby prolonged for forty-eight hours.

In connection with the problem of the saving of injured extremities, the studies of Allen,⁵⁰ Brooks and Duncan⁵¹ and others on the effects of tempera-

ture on the survival of anemic tissues are of great importance. It has been shown that cooling a part with impaired circulation is effective in delaying or preventing the onset of gangrene. There seems to be no doubt that harm may result from surrounding an extremity with defective circulation by containers filled with hot water.

Thus it seems that the treatment of severe injuries of extremities with destruction of part of the main artery should include careful hemostasis, treatment of shock, débridement, chemotherapy, relief of vasospasm by papaverine hydrochloride and sympathetic block, heparinization, cooling of the part and bridging of the defect in the artery, if such is present, by Blakemore's nonsuture method, which employs a vitallium tube lined by a vein. Irrespective of the extent to which one is able to attain the ideal in the treatment of war wounds, the opportunity is certainly available for improvements in the therapy of wounds that are seen in the civilian practice of surgery.

AUTONOMIC NERVOUS SYSTEM

An excellent review of progress in surgery of the autonomic nervous system was recently presented by White,⁵² and the reader is referred to it for details. As White has stated, in no other field is the surgeon more indebted to the contributions of the anatomist and the physiologist. Only the advances in the treatment of peripheral vascular disease and of hypertension will be considered, and the review by White will be quoted freely.

Sympathectomy in Peripheral Vascular Disease

Raynaud's disease. The generally accepted explanation for the typical advanced case of Raynaud's disease is that proposed by Lewis⁵³; namely, that the phenomena of intermittent color changes in the digits are due to abnormal contraction of the arterioles in direct response to cold. The most interesting therapeutic problem is connected with the fact that vasoconstriction is nearly always abolished in the lower extremities after resection of the lumbar ganglia, whereas such was frequently not the case in the upper extremities after resection of the upper dorsal ganglia. It has been shown in man that the highest vasoconstrictor fibers to the upper extremity emerge in the second thoracic nerve and are present in each succeeding anterior root down to the ninth or tenth thoracic level. The difference in the earlier results with upper dorsal and with lumbar sympathectomy seems to have been explained satisfactorily on the basis that postganglionic fibers were interrupted in the dorsal region and preganglionic fibers in the lumbar region. The second and third lumbar ganglia carry only preganglionic fibers to the sciatic nerve, and their removal produces a defect of sufficient length to prevent regeneration. The sympathetic vasoconstrictor fibers must be

ns. In the meantime, the neurosurgeon as well as the osteopath has invaded the field of the orthopedic surgeon, and this is probably a good thing for the patient concerned, including the patient.

In the future every effort will undoubtedly be made to explain the failure to relieve symptoms. It is noted following some of these operations another problem of interest is the role of the cervical intervertebral disk as a cause of brachial neuritis. The absence of compression of the spinal cord. Inter's⁷⁵ opinion on this subject is as follows:

I believe we shall hear more of it in the future and that the number of cases operated on will increase. The problem is still in its infancy, but the number of cases that have been operated on during the past ten years means that it is a real entity and one of considerable importance.

This statement is supported by a recent article by Curling and Scoville.⁷⁹ These problems will be of particular importance in the post-war era.

* * *

As indicated previously, the advances in surgery are so numerous that one can consider only a few of them in a limited time and space. I have chosen those problems that seem of particular interest to me at the moment, and it is likely that others would select an entirely different list. Included among other contributions that might have been considered are the following: the compression treatment of burns; the Orr-Trueta treatment of open wounds and compound fractures; the use of concentrated human serum albumin and of gelatin; the development of thrombin, fibrin foam, and fibrin films; the use of heparin and of dicumarol; the intraintestinal use of poorly absorbed sulfonamides, such as sulfaguanidine and succinylsulfathiazole; the introduction of thiouracil for the treatment of hyperthyroidism and the preoperative preparation of patients who do not respond to iodine; the development of mechanical dermatomes; improvements in transurethral prostatectomy; concentration radiotherapy in the treatment of cancer of the larynx; irradiation of adenoid tissue in the prevention and treatment of deafness; studies on the Rh factor; the recognition and treatment of intracranial aneurysms; the diagnosis and treatment of tumors of the adrenal cortex and medulla; the treatment of Addison's disease by the subcutaneous implantation of pellets of desoxycorticosterone acetate; the intracranial approach to orbital tumors; improvements in mechanical devices for treating fractures; the development of methods that are aimed at stimulating the collateral blood supply to the heart; studies on the pathogenesis and treatment of blast and crush injuries; improved methods for nerve anastomosis; additional methods by which skin grafts may be held in place, the use of vitamin K; the wide employment of tetanus toxoid; and the use of vitallium tubes in the anastomosis of ducts.

Even this long list could be extended almost indefinitely.

One of the most gratifying features of surgery is that the solution of one problem simply opens up additional problems. Churchill⁸⁰ in discussing renal failure in association with injuries stated recently, "It has always fascinated me in clinical surgery to see that as one or more weak links in a chain are strengthened by improved methods of therapy, another weak spot is revealed that becomes recognized only because the chain holds to test it." There are numerous unsolved major problems. For example, it is now technically possible to remove various organs and parts, but it is impossible to replace these structures by those from another person. The technic for transplantation is suitable in most cases, but the part does not survive long in the new host. The solution of this problem would open vast possibilities. It is inspiring to realize that, despite the rapid progress and the many accomplishments in various fields, surgery still offers to investigators and clinical surgeons rich opportunities for work and study.

I am indebted to Drs Alexander Brunschwig, Robert Elman, Henry Harkins and John Lockwood for advice and criticism.

found to be inoperable because of metastases; the report in 1929 of the first correct preoperative diagnosis of insulin-producing islet-cell adenoma by Howland,⁶⁵ with successful extirpation by Graham; the paper by Whipple, Parsons and Mullins⁶⁶ in 1935 that reported successful treatment of carcinoma of the ampulla by partial duodenectomy and excision of a wedge-shaped portion of the head of the pancreas; the report by Brunschwig⁶⁷ of the successful total extirpation of the duodenum and the entire head of the pancreas for carcinoma of the pancreas; the recent report by Priestley, Comfort and Radcliffe⁶⁸ of successful total pancreatectomy for a small-islet tumor, which interestingly enough has been followed by a relatively mild degree of diabetes; and the work of Dragstedt and his associates⁶⁹ with lipocaic. An index to the increasing frequency with which the Whipple procedure or a modification of it is being performed is afforded by the fact that Cattell⁷⁰ has performed seventeen such operations in the last several years.

Problems in operative technic at present center around procedures to reimplant the transected neck of the pancreas into the bowel. It has not yet been finally demonstrated that the successful anatomic implantation affords a functional result. There is some evidence that cicatricial occlusion of the transected neck may prevent its accomplishment. The observation in dogs that pancreatic ducts rapidly regenerate to bowel certainly does not apply in monkeys and has not been demonstrated in man.

Some persons get along normally with completely occluded pancreatic ducts and without the duodenum, others seem to lack full digestive powers for fats and protein but manage to get along well anyway, and still others also lack these powers but do very poorly. Attempts at substitution therapy for pancreatic juice are only partly successful, and here again the situation in animals differs sufficiently from that in man so that the answer can be found only by further clinical investigation.

Cancer of the body and tail of the pancreas is possibly one of the most difficult abdominal cancers that the surgeon has to deal with because it is so often "silent" until an advanced stage. Considerable experience will be necessary to permit an evaluation of what can be accomplished by these operations.

CARCINOMA OF THE PROSTATE

Following the work of Gutman, Sproul and Gutman⁷¹ and others on the prostate-phosphatase relation, Huggins and Hodges⁷² treated a number of patients with advanced prostatic cancer by removal of the testes or by estrogen administration, using as a yardstick the elevated serum phosphatase levels. The reduction in androgens was accompanied by a sharp fall in the amount of acid phosphatase to or toward normal and by a slower rise of alkaline phosphatase, which subsequently likewise decreased.

It was the impression of Huggins that the changes in alkaline phosphatase reflected healing in the lesions in bone. Clinical changes in some of the patients included the relief of pain, an increase in appetite, a gain in weight and a decrease in the size of the neoplasm. In several patients there has been recovery from paralysis that was due to involvement of the spinal cord or nerve trunks with cancer. Huggins⁷³ recently summarized the results as follows:

It must be emphasized that the results are not uniformly successful and that they fall into three groups: one group, less than 5 per cent of patients, received no or slight benefit from endocrine treatment; the other groups, larger and nearly equal in number, obtained respectively an improvement pronounced but unsustained (less than eighteen months) or a pronounced and more prolonged regression of the disease.

In a recent personal communication Huggins stated that about 25 per cent of the patients seem to be completely free of the disease more than three and a half years after orchiectomy.

If one grants that untreated carcinoma of the prostate gland in many cases follows a peculiar course, the observations of Huggins are extremely important. His work casts doubt on the concept of autonomy of the cancer cells, since he has found that in some cases prostatic cancer is dependent on androgen for its survival. The fact that this one type of cancer is sometimes amenable to general methods of therapy encourages one to hope that the same may be true of other forms of cancer.

RUPTURE OF AN INTERVERTEBRAL DISK

There is no problem that has excited wider interest and more controversy in recent years than that of the role of the ruptured intervertebral disk in the causation of low-back pain and sciatica. Middleton and Teacher,⁷⁴ Dandy⁷⁵ and others had described ruptured disks, but it was not until 1934 that Mixter and Barr⁷⁶ reported observations that led to an appreciation of the frequency of the condition. There is considerable difference of opinion concerning the accuracy with which a diagnosis can be made. Most observers are agreed that the introduction of radio-opaque substances into the spinal canal is rarely justified. In the last several years there have been noteworthy improvements in the operative procedure; these include a transition from a complete laminectomy with transdural removal of the disk to a unilateral exposure between the laminae, with removal of little or no bone, depending on the size of the opening, and extradural removal of the disk.⁷⁷

There is no doubt that ruptured disks do occur, and the wide differences of opinion have to do with the frequency of occurrence and the certainty with which an accurate diagnosis can be made. Time and further experience will show that the truth lies between the very reserved position that is taken by most orthopedists and the much more enthusiastic concept that is held by some neurosur-

er low, and R_4 was small and upright. The ie gave a + test for albumin, and the sediment tained 2 white cells per high-power field. The te-cell count was 19,800, with 88 per cent neutro- s. The sedimentation rate was 22 mm. in sixty utes. Two van den Bergh tests were negative : basal metabolic rate was normal. Plain films he abdomen and dorsal spine and gall-bladder lies were normal. The pain was relieved by ng. ($\frac{1}{2}$ gr.) of codeine.

During the next eighteen days the patient im- ved considerably, with almost complete dis-

pulsations were visible in the ascending portion but not in the descending. The back pain subsided somewhat, although movement of the back aggra- vated the pain. The urine cleared up, the white- cell count became normal, and the pulse ranged about 70. The patient was discharged to a nursing home on the thirtieth hospital day.

Second admission (four years later). After dis- charge the patient retired from work but carried on active life until about two months before re- entry, when, following the death of his mother, he noted marked shortness of breath and weakness

FIGURE 1.

pearance of the epigastric pain and fewer sweats. continued to have bilateral back pain. During t period a gastrointestinal series was entirely ative. Films of the chest, nine days after ad- sion, showed definite dilatation of the aorta, ich seemed to be more marked than in the pre- us examination, but whether this was due to the ht rotation of the patient or to actual dilatation ld not be determined. The dilatation was most rked in the upper descending portion, where the meter was almost twice normal. Fluoroscopic

on climbing stairs. He developed a sore throat. For the few weeks prior to admission he had raised considerable gas after eating. During that period he had two attacks of nocturnal dyspnea and found it necessary to use three pillows when sleeping. He had had nocturia (three or four times) but no pain, indigestion, loss of appetite, nausea, vomiting or swelling of the ankles.

Physical examination showed a well-developed, well-nourished man in no distress. The lungs were clear. The left border of cardiac dullness was 10 cm.

CASE 30341

PRESENTATION OF CASE

First admission. A fifty-four-year-old man entered the hospital because of severe epigastric pain.

The patient was apparently perfectly well until a few hours before entry, when he developed a sudden, severe, stabbing pain between the shoulder blades. It was soon noticed in the epigastrium, below and to the right of the umbilicus, and seemed to go through and through. The pain was constant but there were acute exacerbations. Nothing seemed to relieve or aggravate the pain. There were no other symptoms referable to the gastrointestinal, genitourinary and cardiorespiratory systems.

The past history was essentially negative except for an inguinal herniorrhaphy six years before entry.

Physical examination showed a well-developed, well-nourished, restless, slightly cyanotic man complaining of severe abdominal pain. The throat was moderately red. The trachea was in the midline. The lungs were clear. The heart was normal in size. The sounds were bounding, with frequent extrasystoles. The aortic second sound was greater than the pulmonic. The abdomen was distended,

*On leave of absence

with spasm and mild tenderness in the epigastrium but without any palpable masses. There was tenderness to percussion over the lower thoracic spine. The arterial pulsations in the groins and in the feet were of equal intensity.

The blood pressure was 220 systolic, 90 diastolic, in both arms. The temperature was 98.6°F., the pulse 100, and the respirations 20.

Examination of the blood showed a white-cell count of 13,500, with 88 per cent neutrophils. The red-cell count was 5,050,000, with 175 gm of hemoglobin. The urine was acid, with a specific gravity of 1.022, and gave a +++ test for albumin, a ++ test for diacetic acid and a +++ test for acetone. Three to four white cells and red cells were seen per high-power field. Several blood Hinton tests were negative.

X-ray examination of the chest (Fig. 1) showed clear lung fields. The heart shadow was at the upper limits of normal, but the apex was blunted. The aorta showed a moderate degree of tortuosity, with slight dilatation. An intravenous pyelogram was normal.

On the second hospital day the pain was less severe, and located in the epigastrium. It was somewhat relieved by 10 mg. (1/6 gr.) of morphine, together with 0.65 gm. (10 gr.) of aspirin and 30 mg. (1/2 gr.) of codeine. Intravenous fluids were administered. The patient had considerable sweating. He pointed to an area below and to the right of the umbilicus as being occasionally tender. On the third hospital day he complained of epigastric pain and distress. The abdomen became distended, but without tenderness or spasm. The temperature rose to 101°F. The extremities seemed cold and clammy, with profuse perspiration over the rest of the body. The lips were slightly cyanotic. An electrocardiogram revealed frequent auricular premature beats, with a rate of 80 and slight left-axis deviation. T₁, T₂, and T₃ were upright, T₄ was

ys before admission swelling of the ankles appeared and he became progressively more dyspneic. e was seen in the Emergency Ward, where additional digitalis, Mercupurine and ammonium chloride were administered, without any improvement. Physical examination showed a restless, dyspneic man with evidence of recent weight loss. He exhibited Cheyne-Stokes respirations. The skin was cool and moist. There was dullness at the lung bases posteriorly, with decreased breath sounds and tactile fremitus. The heart was about the same size as previously; it was "fibrillating" at a rate of 82. The sounds were booming and distant, and no murmurs were heard. Mild tenderness was elicited to the right of the umbilicus. The liver was palpable two fingerbreadths below the costal margin. Marked edema of the ankles and legs was present.

The blood pressure was 170 to 140 systolic, and 95 to 105 diastolic. The radial pulse was 66, the temperature 98.6°F., and the respirations 25.

Examination of the blood showed a white-cell count of 10,000, with 82 per cent neutrophils. The red-cell count was 5,060,000, with 15.6 gm. of hemoglobin. The urine specific gravity was 1.024, with a ++ test for albumin; the sediment contained 2 or 3 red cells and an occasional white cell per high-power field. The stools were negative. The vital capacity was 52 per cent of normal.

The patient was given a six-meal bland diet without added salts. Fluids were limited to 2000 cc. One-tenth gram (1½ gr.) of digitalis twice daily, as well as ammonium chloride and Mercupurine, was administered. He perspired considerably and seemed to be improving. He was then started on 5 drops of saturated potassium iodide solution daily. In the course of the next ten days the edema almost completely disappeared and the perspiration diminished remarkably. On the twenty-first hospital day, while sitting up in bed, he suddenly clutched his chest and fell back, and died a few minutes later.

DIFFERENTIAL DIAGNOSIS

DR. PAUL D. WHITE: Apparently this patient's pain at its onset was localized in one place. It came on suddenly, starting in the back between the shoulder blades, was quickly noted after that in the epigastrium, and was extremely severe. Naturally one thinks right away that the pain was probably of cardiovascular origin. The story could go with an extensive dissection of the aortic wall, which is suggested by the diffuseness of the spread of the pain and by the sudden onset without other symptoms. I have never encountered a case of myocardial infarction with pain of this distribution. Of course the acute abdominal emergencies must be considered, such as ruptured peptic ulcer, gallstones, mesenteric embolism and even renal colic. But there is no previous story of trouble in the digestive tract or in the urinary tract, and there

was no vomiting. These subdiaphragmatic lesions must be borne in mind, however.

There was slight tenderness in the epigastrium and also in the back. The arterial pulsations in the groins were of equal intensity, all coming through. If there were a dissecting aneurysm of the aorta, one would expect diminished pulsations or the disappearance of the pulsation on one side or the other, as not infrequently happens. Perforation of an aneurysm into the iliac arteries would, however, permit such pulsations to be found in the leg arteries.

This man had hypertension, but there is no note of the blood pressure in the legs. The statement that the arterial pulses were apparently well felt in the legs suggests that there was hypertension there too.

There were occasional red cells in the urinary sediment, but there is no suggestion of active bleeding, such as one might expect with a renal calculus or infarct. And there was no history of hematemesis to point to a peptic ulcer.

The x-ray examination gives some indication of a hypertensive heart, but it was not very large—possibly in an early stage, with 100 gm. or so of extra weight, which produced little change.

The prolonged pain is not particularly diagnostic. We have no note about morphine on the first day.

DR. BENJAMIN CASTLEMAN: He was given 15 mg. (¼ gr.) of morphine when he first entered the hospital.

DR. WHITE: The electrocardiogram was essentially normal. It is hardly likely that acute coronary occlusion had occurred, but the record is consistent with the other diagnoses mentioned.

There was considerable, but not extreme, leukocytosis.

By fluoroscopy, pulsations were visible in the ascending portion of the aorta but not in the descending portion. I am not sure about the importance of that difference. I think that normally one sees pulsation more readily in the ascending portion of the aorta than in the descending.

DR. GEORGE W. HOLMES: I have selected some of the films that looked rather significant. This film, taken in 1940, shows hypertensive changes, a tortuous aorta and a round left border of the heart, which usually means hypertrophy of the left ventricle. It also shows rather bright lung fields, with a low diaphragm. In the oblique view, one can distinctly see the outline of the aorta; there is a good deal of magnification in this position, and the estimate of size is not too accurate. I can safely say that the patient had some dilatation of the aorta, not saccular or anything that one might interpret as an aneurysm. An abdominal film taken at that time shows part of the liver quite well, and I think that he had an enlarged liver. I cannot see anything definite in the gastrointestinal tract, and I judge from the report that it was negative. In

to the left of the midline in the fifth space. The auricles were fibrillating. The abdomen was negative.

The blood pressure was 198 systolic, 120 diastolic. The temperature was 98°F., the pulse 65, and the respirations 25.

Examination of the blood showed a hemoglobin of 13.6 gm. The nonprotein nitrogen was 30 mg. per 100 cc. The urine had a specific gravity of 1.024, with a +++ test for albumin, and the sediment contained many coarsely and finely granular casts, 20 white cells and 4 red cells per

Barium passed after some delay through the pylorus, filling a rather large duodenal cap, in the center of which a 0.8-cm. ulcer crater was visible. An electrocardiogram showed auricular fibrillation, with an average rate of 70. T_1 was inverted, ST_1 , ST_2 , and ST_4 were sagging, T_1 and T_2 were upright, and T_4 was sagging. There was slight left axis deviation.

The patient was given 0.1 gm. ($1\frac{1}{2}$ gr) of digitalis daily, as well as 0.1 gm. ($1\frac{1}{2}$ gr.) of aminophyllin. He was placed on a three-stage gastric diet, with 15 drops of tincture of belladonna after

FIGURE 2.

high-power field. A Hinton test in dilutions and a Wassermann test were negative. X-ray examination of the chest (Fig. 2) showed the heart markedly enlarged and particularly prominent in the region of the left ventricle. The aorta was extremely tortuous and was moderately dilated, particularly in the descending portion. A gastrointestinal series showed marked tortuosity of the esophagus, apparently due to adhesions of the esophagus to the arch. In the stomach, along the lesser curvature and opposite the angulus, a crater-like niche was sometimes demonstrated on compression.

meals. He did well. A gastrointestinal series sixteen days later did not demonstrate the lesion along the lesser curvature or a definite ulcer crater in the duodenum. He was discharged on the twenty-second hospital day.

Final admission (forty-eight days later). Following discharge the patient was asymptomatic, but one month before entry he developed diffuse lower abdominal pain that was not relieved by eating. He experienced increasing exertional dyspnea, almost nightly episodes of paroxysmal dyspnea and daily pain in the upper anterior chest. Ten

DR. ALLEN: So he did; but they do not mention afterward. Did it have any bearing, Dr. Jones?

DR. JONES: It is entirely possible that the pain was vascular in origin.

DR. WHITE: Does one get such diffuse pain in cases of mesenteric embolism?

it was considered in the differential diagnosis, we did not believe that he had mesenteric thrombosis.

DR. WHITE: I suppose that he would have had more abdominal evidence.

DR. ALLEN: Yes, I believe he would.

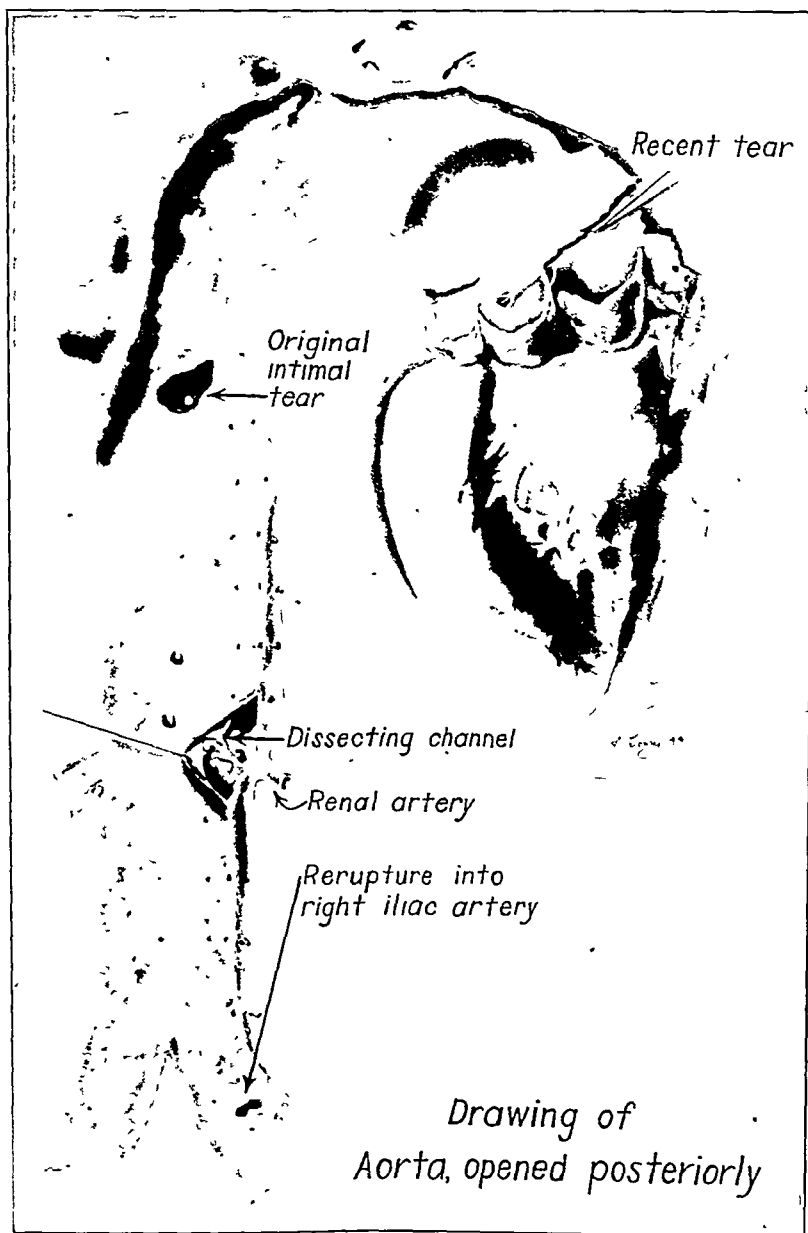

FIGURE 3

DR. ALLEN: The pain of mesenteric thrombosis is a little different in distribution as a rule. This pain was between the shoulder blades, which is a peculiar place to get pain caused by mesenteric thrombosis. If one is suspicious of that diagnosis, more is learned by the examination of the abdomen. Although

CLINICAL DIAGNOSES

Hypertensive heart disease.
Dilated aorta (?dissecting aneurysm of aorta).
Duodenal ulcer.
Thyrotoxicosis?

the 1944 films there is a marked change in the size of the heart but not in the shape. The aorta appears much as it did before: there is unusual tortuosity with some widening. I do not recall having seen many cases of hypertensive heart disease with such a large aorta. Also, it is wider in one place than in others.

DR. WHITE: The second admission was four years later. Nocturnal dyspnea appeared and increased, apparently the beginning of left ventricular failure in hypertensive heart disease. It is characteristic for these patients to have insomnia from pulmonary congestion, a point often overlooked. It might be well to point out that he still had a moderate degree of hypertension while in bed. I do not believe that we can use the blood pressure readily in differential diagnosis. A number of patients even with acute myocardial infarction have a higher blood pressure during pain than at any other time of their lives.

The red cells in the urinary sediment indicate either congestive heart failure or hypertensive renal involvement, or both.

The Hinton test was negative. They were looking hard for aortic dilatation with reference to syphilis. A gastrointestinal series showed marked tortuosity of the esophagus, apparently due to "adhesions of the esophagus to the arch." I am not familiar with that point. It is very interesting and one wonders whether it was due to aortic disease or to some mediastinal involvement.

DR. HOLMES: Tortuosity of the esophagus is not uncommon in elderly people. It does occur in some cases of chronic mediastinitis.

DR. WHITE: An inverted T₁ may be found in the electrocardiogram with either chronic hypertension or coronary heart disease. It does not necessarily mean coronary heart disease as we once thought it did. The sagging could have been the result of a digitalis effect. We do not know whether he had received digitalis before, but the patient was getting 0.1 gm. daily shortly after he had presumably been digitalized.

There was an interval of sixteen days between the two gastrointestinal series. Could the crater of a duodenal ulcer have completely healed in that short time? Perhaps one report or the other is in error.

DR. HOLMES: I think healing could have taken place in that length of time.

DR. WHITE: If he had had a duodenal ulcer could it have produced his symptoms? Not necessarily, nor his earlier ones either. I have no idea why he had abdominal pain unless perhaps it was from liver engorgement, spoken of later, which can sometimes give rise to pain in such a low position. The blood pressure was dropping, likely associated with a higher degree of heart failure.

The fluids were limited to 2000 cc. daily; 1500 cc. might have been better.

He was started on 5 drops of a saturated solution of potassium iodide. Why?

He did not die immediately, and death was not due to angina pectoris. There may have been an acute coronary occlusion, or ventricular tachycardia, or further dissection of the aortic wall, with rupture. I do not believe that a definite answer is possible concerning the exact nature of the final episode.

As for the final diagnosis, the patient certainly had hypertensive heart disease, with a big left ventricle and congestive heart failure. A healed dissecting aneurysm of the entire descending aorta with perforation into one of the iliac arteries, four years old, is quite probable, although it is almost too good a diagnosis to be true. A chronic double-barreled aorta is thought to be an extremely rare condition, but it was found in more than a quarter of Shennan's* 300 cases of dissecting aortic aneurysm, that is, a healed dissecting process with a double aorta. A duodenal ulcer, healed or healing, and terminal aortic rupture are also probable.

DR. J. H. MEANS: I can answer Dr. White's question about the potassium iodide. This man had staring eyes, lid lag and so on, and we wondered if, in addition to the rest of the picture, he had thyrotoxicosis. We thought it best to find out what his basal metabolic rate was. It was not diagnostic, but I thought it would do no harm to give potassium iodide on the possibility that he had thyrotoxicosis.

DR. CHESTER M. JONES: I should like to ask whether there is any evidence that potassium iodide is of value in the treatment of hypertension.

DR. WHITE: I believe not.

I should like to ask Dr. Allen to comment on the diagnosis of an acute abdominal emergency at the time of the first admission.

DR. ARTHUR W. ALLEN: I saw this patient in consultation at the time of the first admission, and I am afraid that I contributed little, aside from the fact that, to my mind, the case did not represent an acute abdominal emergency. I hazarded a possible diagnosis, which finally proved to be partially correct, and I also seriously considered the question of perforated ulcer. I do not recall all the physical findings, but I did not believe that the abdomen was boardlike enough to justify the diagnosis.

While I am speaking of this, I should like to ask whether the pain in the right lower quadrant could have had any bearing on the establishment of decompression of the aneurysm. If he had a fistula of the iliac artery, could that have been the cause of the pain in the right lower quadrant?

DR. WHITE: A dissecting aortic aneurysm, if that is the situation here, can explain almost any kind of pain because of the multiplicity of the vessels that can be involved. When this patient was first examined, however, he had a good femoral pulse.

*Shennan, T. *Dissecting Aneurysms*. Medical Research Council, Special Report Series, No. 193. London. His Majesty's Stationery Office, 1934.

the axillary line (Fig. 1). There was no hydro-orax. She improved in the next few days, but a repeat x-ray examination of the chest five days later showed little change in the appearance of the lungs. The density in the right lower lung field appeared to be confined to the right middle lobe. The trachea was extremely narrow, which had apparently been noted on one or more previous examinations. Flecky calcification was seen over the dome of the right diaphragm. The left costophrenic angle was obliterated. The improvement continued until seven days before entry, when she had a sudden attack of sharp pain in the right chest without fever or chills. She had a feeling of fullness

and pinpoint, and did not react to light or accommodation. The extraocular movements were normal. The tongue was dry, rough and red. The neck was stiff. The chest was barrel shaped. Over the right base posteriorly there was dullness, with bronchial breathing, diminished tactile and vocal fremitus and many rhonchi and rales. The left border of cardiac dullness was 8.5 cm. to the left in the fifth space. A Grade II apical systolic murmur was heard over the precordium but was not transmitted. The abdomen was mildly distended with gas. Some voluntary and involuntary generalized spasm was present. Peristalsis was diminished, and there was some tinkling of the peristaltic sounds. Consid-

FIGURE 1.

in the pit of the stomach but no nausea or vomiting. The pain was relieved by the application of heat. She visited the clinic two days later, but refused hospitalization and returned home. She apparently stayed in bed, without eating or drinking much, gradually became disoriented and was found in a state of semicoma. She was then admitted to the hospital.

Four years before admission she had been treated for pernicious anemia. During that period she was discovered to have positive blood Hinton and Wassermann tests. About eighteen months before admission the spinal fluid was negative. She had had no history of primary or secondary manifestations of syphilis, and no treatment was given.

Physical examination showed a thin, poorly nourished, semicomatose woman. The skin was moist and warm. The pupils were round, regular

and mottling and cyanosis of the feet and fingers were noted. Neurologic examination revealed a right facial paralysis. The tendon reflexes of the left arm were more active than those of the opposite arm or of the legs; the plantar reflexes were normal.

The blood pressure was 180 systolic, 84 diastolic. The temperature was 99.2°F., the pulse 100, and the respirations 24.

Examination of the blood showed a red-cell count of 3,620,000, with 14.6 gm. of hemoglobin. The white-cell count was 23,800 with 98 per cent neutrophils. The urine specific gravity was 1.016, and the reaction pH 4.5; it gave a +++ test for diacetic acid.

The patient was placed in an oxygen tent and given 10 cc. of aminophyllin intravenously and 500 cc. of 5 per cent glucose in physiologic saline solution. She died nine hours after admission.

DR. WHITE'S DIAGNOSES

Hypertensive heart disease, with left ventricular enlargement.
 Congestive heart failure.
 Healed dissecting aneurysm of aorta.
 Peptic ulcer?
 Terminal rupture of aorta, with further dissection?

ANATOMICAL DIAGNOSES

Dissecting aneurysm of ascending aorta, recent.
 Dissecting aneurysm of descending thoracic aorta, healed, with rupture into right iliac artery.
 Cardiac hypertrophy, hypertensive type.
 Hydrothorax, bilateral.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy showed a hypertensive heart weighing over 800 gm. and there was about 600 cc. of clear, straw-colored fluid in each pleural cavity.

In the first portion of the descending thoracic aorta we found a large hole in the intima, which was smooth and shiny, certainly not ragged (Fig. 3). This communicated with a dissecting channel that went all the way down the aorta and re-entered the original stream at the origin of the right iliac artery, as Dr. White predicted. Here also the edges of the opening were smooth and shiny, indicating that the process was not recent. This old dissecting aneurysm had developed a new intimal lining, on top of which arteriosclerosis had been superimposed. Apparently the initial intimal tear, which occurred presumably in 1940, produced the bulging aneurysmal sac that was seen in the x-ray films. This aneurysm, which at first glance looked like the ordinary syphilitic aneurysm, was filled with a laminated thrombus, all of which was within the media and part of the dissecting process.

Just beyond the arch was another smaller but similar bulge, which also had an intimal opening. There was no communication between the two at the time of autopsy, and neither of them had ruptured externally. The dissecting aneurysmal sac had dissected around the mouths of the renal, intercostal and inferior mesenteric arteries and had lifted up the intima to produce some narrowing. There was, however, no dissection along these arteries.

The terminal event was an acute dissection of the aorta in the ascending portion, which is the commonest location. The intimal tear was transverse and was located just above the valve. It had dissected distally to include the arch and proximally as far as both coronary mouths. There was no external perforation, so that the sudden death may have

been anginal, owing to constriction of the coronary orifices.

DR. MEANS: I should like to ask Dr. White and Dr. Castleman if they think that the administration of iodide contributed to death by softening the aorta.

DR. CASTLEMAN: I doubt it.

DR. WHITE: So do I.

I should again like to call attention to the monograph written ten years ago by Dr. Shennan, of London. He reported 300 cases, 79 of which were old healed aneurysms. I looked them up last night because I was interested in how the patients died. I found a variety of ways, but most of them died of heart failure.

DR. ALLEN: Did any die because a surgeon tried to establish an iliac opening?

DR. CASTLEMAN: That has been tried in New York. The man lived a week.

DR. MEANS: What do you think the course of the blood was after this first aneurysm had taken place? Was the aneurysm acting as a channel as well as the aorta?

DR. CASTLEMAN: Without any question, but the aneurysm was small.

CASE 30342

PRESENTATION OF CASE

A sixty-four-year-old woman, a domestic, was brought into the hospital in semicomatose.

The patient was known to have had high blood pressure (230 systolic, 100 diastolic), an enlarged heart and a more or less chronic cough for several years. She had had dyspnea on exertion for the ten months before entry, during which period she had received 0.1 gm. (1½ gr.) of digitalis three times a day for one week, followed by 0.1 gm. daily. She was well except for occasional episodes of upper respiratory infection and cough. About seven months before entry, after one of these episodes of upper respiratory infection, cough and dyspnea, she was examined in the Out Patient Department, where x-ray films showed no unusual findings except for an enlarged heart. She was treated for cough and continued to receive 0.1 gm. of digitalis daily. Three weeks before entry, following another attack of upper respiratory infection in which she experienced considerable dyspnea, a feeling of extreme weakness, and cough productive of white phlegm, she was again seen in the clinic, where examination showed diminished breath sounds over the right lower lung field, with occasional expiratory squeaks. At that time the blood pressure was 220 systolic, 100 diastolic. The temperature was 99°F.; the pulse was 84 and regular. X-ray examination of the chest showed extensive increased density along the right border of the lung parallel to the diaphragm, and reaching from the lower aspect of the hilus almost to

he lobe was not smaller than normal, and even though no fever and cough are mentioned in the record, I think that they were overlooked. A white-cell count of 23,000 and 98 per cent neutrophils are definite signs of infection. I am no neurologist but looked up a few things and believe that the cranial-nerve signs on one side and the hemiplegia on the opposite side, the contracted, rigid pupils and the stiff neck are consistent with a lesion in the pontine area. Therefore I am going to say that this woman had a pneumonia of the right middle lobe, and that she developed suppuration in that lobe and that she died of a metastatic brain abscess in the pontine region.

DR. FREDERICH KLEMPERER: I followed this patient for the three years before entry. When I first saw her she was being treated for pernicious anemia and syphilis. It is questionable whether she ever had pernicious anemia, because when specific treatment was discontinued the red-cell count did not come down; in fact she had not received liver extract for three years. Antisyphilitic treatment was discontinued because of her generally poor condition — the marked hypertension and the fact that she was in and out of mild cardiac failure. The spinal fluid was negative. She had some neurologic signs — absent knee jerks and markedly diminished ankle jerks. She complained about paresthesias in the legs, but sensory examination was negative. The neurologic findings have never been explained.

I last saw her about ten days before she died, when she gave a story of cough and malaise, which had markedly improved by that time. X-ray examination was said to have shown atelectasis of the lower lobe, and I urged her to enter the hospital, but she refused. My impression was that she had either pneumonia or infarct and that the prognosis was poor.

DR. J. H. MEANS: Was a lumbar puncture done?

DR. KLEMPERER: Not at that time; the one done two years before was negative.

DR. MEANS: Did she have a positive Kernig sign as well as a stiff neck?

DR. KLEMPERER: Not so far as I know.

DR. MEANS: I suppose that the final episode was not related to the pulmonary situation. She may have had some kind of subarachnoid hemorrhage.

CLINICAL DIAGNOSES

Bronchiogenic carcinoma?
Bronchopneumonia?
Cerebral hemorrhage.

DR. PITTMAN'S DIAGNOSES.

Pneumonia, right middle lobe, with suppuration.
Metastatic brain abscess (pontine).

ANATOMICAL DIAGNOSES

Lobar pneumonia, right middle lobe (pneumococcus, Type 14).

Empyema (pneumococcus, Type 14).

Bacteremia (pneumococcus, Type 14).

Cerebral thrombosis, recent: left internal carotid artery.

Syphilitic aortitis.

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: The autopsy on this patient showed an extensive empyema in the right chest, limited almost entirely to the region of the lower lobe. After the pus was aspirated we found that the middle lobe was completely solid. On section it showed the characteristic gray hepatization of lobar pneumonia. This process had extended partly into the right lower lobe; the lower portion of the lower lobe was not involved but was collapsed.

Microscopic examination showed a process that I do not believe could have been three weeks old; it probably began when she complained of pain in the chest about a week before she entered the hospital. What the process was at the time of the second x-ray film I cannot be sure. She may well have had an acute bronchitis with some atelectasis in the region in which the lobar pneumonia subsequently developed. We were able to recover a Type 14 pneumococcus from the pleural pus and the blood.

In the brain we found a fresh thrombus in the left internal carotid artery, with early softening of the cerebral hemisphere on that side. The bone marrow showed hyperplasia of the myeloid elements but no evidence of red-cell hyperplasia, so I think that we can rule out pernicious anemia.

She did have evidence of syphilis in that we found a mild aortitis with some narrowing of the coronary mouths.

DR. HOLMES: Was the trachea narrowed?

DR. CASTLEMAN: Yes, but we could not determine the cause; perhaps it was congenital.

DR. MEANS: Could you connect the cerebral and pulmonary affairs?

DR. CASTLEMAN: There was no infection in the brain.

DR. HOLMES: In the last film there is some evidence of fluid in the pleural space, but nothing like what you describe.

DR. CASTLEMAN: That film was taken the day before death. The empyema must have been present for at least three or four days, if not longer.

DIFFERENTIAL DIAGNOSIS

DR. HELEN PITTMAN: This woman had a great many things the matter with her, and the first point is to try to decide which are relevant to the terminal illness. She had apparently been treated for pernicious anemia four years before. I do not believe that that had much to do with the last episode. She was known to have positive blood tests for syphilis four years before, but a spinal-fluid tap eighteen months before entry was negative, and so long as she had no history of primary or secondary manifestations of syphilis and no treatment given, it is probably safe to assume that the pupils were not pinpoint and did not fail to react at that time. Discarding these things, we come to the final illness. She had been known to be hypertensive, with a large heart and more or less chronic cough, for a good many years. She had been ill for three weeks but had been well enough to come into the Out Patient Department and well enough to refuse hospitalization a week before she was brought in semicomatose to die in nine hours.

I am particularly anxious to see the x-ray films because apparently we can assume that the lung fields were negative until three months before the present illness, despite the fact that she had had a chronic cough for a good many years.

DR. GEORGE W. HOLMES: The diaphragm is high and the heart lies more or less horizontally in the chest, which tends to increase the size of its shadow regardless of the size of the heart. On the other hand, the curve of the left ventricle is prominent and enlargement is definite. In the lateral view the anteroposterior diameter of the chest is obviously increased, and the patient probably had some emphysema. Except for the low diaphragm and the absence of limitation of movements this is the type of chest that one sees in asthmatics.

In the area along the right border of the heart there is a definite change. From a right border well within normal limits in the first film, there is in the later film an indefinite hazy shadow that spreads out along the level of the diaphragm. In the lateral view this shadow lies in the anterior part of the chest and is thus in the region of the middle lobe. The other shadow, which extends along the axillary border, makes one suspect that fluid was present.

DR. PITTMAN: What do you think about the size of the lobe? Is it normal?

DR. HOLMES: There is little evidence of collapse. The diaphragm is not in the usual position. The heart, if anything, is away from the lesion rather than toward it, and there is no increased aeration in the portion of the lung above it, which ought to occur. I do not believe that there is any definite evidence of bronchial obstruction.

DR. PITTMAN: Do you see anything in the oblique view that you could possibly interpret as a cavity?

DR. HOLMES: The details do not show up well in this light, but there is no definite evidence of a

cavity. There are areas of calcification; I do not know what they are, and they are probably of no importance.

DR. PITTMAN: Do these shadows indicate dilated bronchi?

DR. HOLMES: I should not care to commit myself.

DR. PITTMAN: This is one of the times when the description of the films adds little to the description previously given. The question is, Which set of systems are we going to blame for this woman's final illness? She had a middle-lobe process. We have seen a great many middle-lobe pneumonias this year, but the patients either have recovered or still have something going on in the middle lobe without serious trouble.

This woman had a three-week illness, and we are told that she had an x-ray film taken seven months before entry that was essentially normal. The dry, rough, red tongue was, I assume, the tongue of dehydration, malnutrition and avitaminosis. I do not believe that it was the tongue of pernicious anemia. The blood pressure apparently dropped a good deal, which is not surprising. The patient entered the hospital semicomatose, with small pupils that did not react, a stiff neck and right facial paralysis, and these rather impressive signs point to something in the central nervous system. She had slight fever, and the pulse and respirations were only slightly elevated. She had a definitely elevated white-cell count—23,000, with 98 per cent neutrophils. The urinary findings I attribute to her nutritional state. The process in the chest was rather extensive, and yet I do not recall that any comment was made about cough or whether she was raising any sputum at the time of admission. With as much of a process in the chest I should have expected her to have cough and to be producing sputum. If sputum was not being raised because of bronchial plugging, I should have expected an elevation of temperature comparable to the leukocytosis of the blood.

So we come down to trying to decide whether this woman's terminal episode, which I am quite sure was cerebral, was on a vascular basis in a patient with known hypertension of many years' duration or due to infection. Whether she had a cerebral hemorrhage accompanying this pulmonary process or whether the terminal lesion was on some other basis, I do not know. I tried to see if I could get any leads from Dr. Holmes that would give a reasonably good cause for postulating a lung abscess. The chest was clear enough six months after entry to make us reasonably sure she did not have a long-standing bronchiectasis. We do know that one of the dangerous complications of lung abscess is cerebral metastasis and that this is one of the most frequent causes of death in such cases. Here, however, we have slim evidence on which to make a diagnosis of lung abscess. There was a definite process in the chest, which did not shrink the lung.

curring in building and equipping its hospitals; paid physicians' salaries ranging from \$4800 to \$14,000 and totaling \$500,000 per year; paid a similar total to staff nurses at the rate of \$150 to \$200 a month; provided the health-plan members with one of the most comprehensive coverages ever attempted; and treated a group of people definitely below par physically. No physical examinations were possible under union contract, but even if permitted, the shipyards would have been forced to employ practically all these workers because of the shortage of manpower.

The report goes on to mention the distrust with which the medical profession first looked on this financial plan. Gradually the profession became more tolerant as they recognized the tremendous load that the organization was carrying and the extraordinary conditions under which its job was being done.

The author of the report also goes on to discuss the future of the organization and the factors on which its continued existence must depend. The advantages to the workers and to the physicians of maintaining this or a similar medical service are enumerated. Details are also given concerning the quantity and quality of medical care furnished during the period covered by the report.

This report makes impressive reading and warrants more than a glance by physicians who are interested in the socioeconomic aspects of medical practice. Those who are now actively concerned with the problems of prepaid health and medical-care insurance may find it useful to adopt some of these methods and principles in order to obtain the most effective and efficient medical service to large numbers of people at low cost—and at the same time to maintain the high standards and dignity of the medical profession.

The conditions that make possible the establishment and maintenance of such an organization, however, appear to be comparable to those that occur in the Army and the Navy; that is, a large number of people in relatively good financial standing are herded into a new environment. What will happen when this wartime industry is disbanded or decentralized? How can this type of service be adapted to communities where reasonably adequate

medical and hospital facilities already exist, where many of the inhabitants seek hospitalization in terms of race and religion as well as medical competence and where they are working under the usual ups and downs that characterize small or moderate-sized industries? Can established practitioners and specialists adapt themselves to this type of medical care without serious disruption of such services? These are merely a few of the problems involved in adapting the Permanente setup to the one hundred and thirty million people of this country and to the doctors who must serve them.

SUTURE MATERIALS

OVER fifty years ago Halsted¹ described the fine silk suture technic in clean surgical operations and attested to its safety and efficacy. The method was accepted by few surgeons at that time, probably because it entailed such painstaking procedures and was so time consuming. Through the influence of Halsted's many pupils, however, as they scattered through the country and undertook important responsibilities, the technic gradually spread so that after forty years there were many nuclei, particularly in the teaching institutions, where this method of suturing was exactly carried out. At about that time the meticulous experimental work of Howes and Harvey² showed that catgut sutures, as they were then made and used, frequently disintegrated before the sutured tissues had gained any appreciable tensile strength through the processes of repair. In spite of this, catgut still continued to be used in the vast bulk of surgical practice.

Four years ago, Meade and Ochsner³ demonstrated that fine cotton sutures could be used in the same way that fine silk sutures had been used, and with equally good or better results. They also showed that the "lag period" in healing was reduced and that there was no period subsequent to suture when a wound in a healthy animal, correctly sutured with cotton, was any weaker than it was when the sutures were first placed. They also demonstrated that, even if a wound sutured in this way became infected, a permanent draining fistula associated with infection about the knots did not necessarily result, provided the cotton was not used for a continuous suture and provided that extremely fine

PREPAID MEDICAL CARE A LA KAISER

THE Permanente Foundation Hospital has recently published its first annual report.* Starting with 6 physicians and 6 nurses on March 1, 1942, it opened offices in Oakland, California, and began to render industrial medical care to 20,000 men of two of the Kaiser shipyards. By the end of February, 1943, it was serving 90,000 workers and comprised a staff of 62 doctors, 241 nurses and 324 miscellaneous employees. It then had available 209 hospital beds, and construction of a 100-bed addition was begun later in the year. Three issues of the *Permanente Foundation Bulletin*, which contain

*Garfield, S. R. First annual report of the Permanente Foundation Hospital. *Permanente Found Bull* 2:35-48, 1944.

eighteen papers reporting clinical experience at the hospital by members of its staff, had already been published, and many other articles have appeared in various medical journals. These indicate a high standard of medical practice.

Some of the features of the report are worthy of study by all those interested in improving the standards of medical care and in providing it at a low cost to low-income and moderate-income groups. The history of the Permanente Foundation, its relations with the local medical profession, its financial statement and the medical services that it offers are reported in some detail. Some excerpts are as follows:

Our medical service and the Foundation were necessitated by the same motivating force that created the medical program for the armed services. That force was the displacement of masses of people to areas where existing medical and hospital services were inadequate.

We find that, where production for war created tremendous shifts in population, in the majority of instances medical and hospital care for these people was entirely forgotten. This was not so, however, where the armed forces directly entered production; for example, in Navy shipbuilding yards, Navy physicians, in uniform, were responsible for the care of the workers' health. When private industry was given the job, no such care was provided.

The Kaiser organization had . . . a knowledge acquired from past experience in providing medical and hospital care in industry. . . [It] had been engaged prior to the war in building huge construction projects in isolated areas such as Coulee Dam. With no pre-existing medical and hospital facilities available, these had to be provided to the many people employed. By trial and error, a method of highly satisfactory service was worked out through the years. After Pearl Harbor when the influx of war workers into the Richmond-Oakland area created a similar lack of hospital and medical facilities, it was evident that the tested solution which experience and time had proven efficient should be put into effect.

As a result Permanente Foundation was born. A charitable trust, with a Board of Trustees, headed by Mr. and Mrs. Henry J. Kaiser, registered in Alameda County, California, was set up in such a manner that there would be no profit incurred by anyone in the Kaiser organization. Any funds that may be accumulated by the Foundation must be used only for such charitable purposes as: medical research, provision of facilities in needy areas, medical care for the poor, rehabilitation of men returning from the war and so forth.

Economically, the results have been rather amazing. In spite of wartime difficulties, with the associated high cost of supplies and high salaries, while receiving only pre-war income from the employees, the Foundation has accomplished the following: retired \$500,000 of the debt of \$700,000

unction has been translated into the well-accepted principle that no person with positive sputum should be allowed to remain in a household where there are children. Too long, however, the danger of tuberculosis among school personnel has been overlooked although the school ranks immediately after the home in importance in the life of a child. The following statements, abstracted respectively from two recent publications (Laberge, L. *Detection of tuberculosis in schoolteachers in the Province of Quebec. Canad. Pub. Health J.* 34:125-129, 1943 and *Tuberculosis Control in the Schools of New Jersey*. Compiled by the New Jersey Tuberculosis League, co-operating with the State Department of Public Instruction, January, 1944) emphasize the problem.

* * *

The Legislative Assembly of the Province of Quebec on May 17, 1941, unanimously passed an act stating that no person can teach in a public, private or independent school unless he produces every year a physician's certificate stating that he "suffers from no infirmity or disease which renders him unfit for teaching" and "a certificate from a phthisiologist attesting that a clinical and radiological pulmonary examination shows that such person is free from tuberculous disease." Such examination must be made within two months following the engagement. Should any teacher prove to be tuberculous the contract to teach is immediately rescinded.

If Quebec glories in being the first province in Canada to pass such a law it must be admitted that it is the one to need it most — having the highest death rate from tuberculosis among the Canadian provinces. Three factors led to the passage of the law. First, a three-year educational campaign on tuberculosis that reached most of the population; second, a law passed by the City of Quebec requiring all teachers of the School Commission to undergo examination for tuberculosis, including films of the chest (out of 523 teachers examined 16 were withdrawn from teaching because of active or chronic tuberculosis). The third factor was a personal experience published in an educational review, which demonstrated mass contamination of pupils by a tuberculous teacher.

The legislation was introduced by the Council of Education, of which all the bishops of the province are members, so the doors of the teaching religious congregations were thrown open.

Difficulties arose in the enforcement of this new law as was to be expected, but these were overcome as the organization proceeded. In rural districts the expense was borne by the Board of Health, and in Montreal the Catholic and Protestant school commissions paid for the x-ray films.
